

Remote Imagery

A Technical Treatise

Compiled By
David Childers

Foreward

According to Wikipedia, remote sensing is the ability to acquire information about an object without making physical contact in contrast to obtaining information via on-site examination. This acquired information can be composed of several types, which depends on the actual data requirements.

Remote imagery is composed of photographic image data acquired by distant methods, such as satellite or aircraft. This photographic imagery can also be divided into several classes, such as spectral, infrared, color, black, and white. The information required from the imagery generally dictates the type of imagery data used.

Remote imagery requires the ability to fully interpret or analyze the graphical representation to understand the information provided within the image's context. This informational context can provide details regarding structure locations, vehicle or pedestrian travel areas, vegetative cover areas, soil conditions, or locations of bodies of water such as lakes, rivers, or streams.

Remote imagery should be an essential element within any civil engineering project's research and planning objectives, whether it is new construction or modifications of an existing structure. Remote imagery can provide insightful information to the project manager, engineering, architectural design, and environmental services team. Ground-level site observations can yield a limited amount of data, whereas aerial observations can provide a comprehensive understanding of the site and environmental requirements. Pre and post imagery analysis can also provide detailed information that can be used as a basis for future project planning in surrounding areas.

With the enhanced environmental requirements being implemented at the Federal, State, County, and City level, it is essential to have all relevant information available to facilitate proper planning to safeguard the proposed project site's environmental conditions. Detailed project site imagery can also provide a wealth of information for planning the work site entrances, exits, storage, and specialty work areas.

As the old adage goes, "An ounce of prevention is worth a pound of cure," remote imagery can provide managers, supervisors, and workers with an enhanced understanding of relevant site conditions that may not be easily observed or understood otherwise.

It is my sincere wish that the reader will gain both insight and knowledge from the contents of this publication.

David Childers

Executive Summary

The purpose of this treatise is to collate technical information applicable to the field of Remote Imagery. Remote imagery is the ability to capture detailed graphical imagery information of locations and or objects.

The following areas are covered in detail:

- Functionality.
- Methodology.
- Analysis.
- Usage.

REMOTE SENSING

1. **Purpose.** This EM is intended to promote effective use of remotely sensed data by all USACE divisions and districts.
2. **Applicability.** This EM applies to all HQUSACE elements and USACE commands responsible for integrating remotely sensed and geospatial data into Civil Works Projects.
3. **Distribution.** Approved for public release, distribution is unlimited.
4. **References.** References are listed in Appendix A.
5. **Discussion.** The theory, practice, and use of remote sensing are comprehensively presented in this EM. Focus is placed on the U.S. Army Corps of Engineers 9 - Civil Works Business Practice Areas.

Chapter 1

Introduction to Remote Sensing

1-1 Purpose of this Manual.

a. This manual reviews the theory and practice of remote sensing and image processing. As a Geographical Information System (GIS) tool, remote sensing provides a cost effective means of surveying, monitoring, and mapping objects at or near the surface of the Earth. Remote sensing has rapidly been integrated among a variety of U.S. Army Corps Engineers (USACE) applications, and has proven to be valuable in meeting Civil Works business program requirements.

b. A goal of the Remote Sensing Center at the USACE Cold Regions Research Engineering Laboratory (CRREL) is to enable effective use of remotely sensed data by all USACE divisions and districts.

c. The practice of remote sensing has become greatly simplified by useful and affordable commercial software, which has made numerous advances in recent years. Satellite and airborne platforms provide local and regional perspective views of the Earth's surface. These views come in a variety of resolutions and are highly accurate depictions of surface objects. Satellite images and image processing allow researchers to better understand and evaluate a variety of Earth processes occurring on the surface and in the hydrosphere, biosphere, and atmosphere.

1-2 Contents of this Manual.

a. The objective of this manual is to provide both theoretical and practical information to aid acquiring, processing, and interpreting remotely sensed data. Additionally, this manual provides reference materials and sources for further study and information.

b. Included in this work is a background of the principles of remote sensing, with a focus on the physics of electromagnetic waves and the interaction of electromagnetic waves with objects. Aerial photography and history of remote sensing are briefly discussed.

c. A compendium of sensor types is presented together with practical information on obtaining image data. Corps data acquisition is discussed, including the protocol for securing archived data through the USACE Topographic Engineering Center (TEC) Image Office (TIO).

d. The fundamentals of image processing are presented along with a summary of map projection and information extraction. Helpful examples and tips are presented to clarify concepts and to enable the efficient use of image processing. Examples focus on the use of images from the Landsat series of satellite sensors, as this series has the longest and most continuous record of Earth surface multispectral data.

e. Examples of remote sensing applications used in the Corps of Engineers mission areas are presented. These missions include land use, forestry, geology, hydrology, geography, meteorology, oceanography, and archeology.

f. A glossary of remote sensing terms is presented at the end of this manual, also see <http://rst.gsfc.nasa.gov/AppD/glossary.html>.

g. The Remote Sensing GIS Center at CRREL supports new and promising remote sensing and GIS (Geographical Information Systems) technologies. Introductory and advanced remote sensing and GIS PROSPECT courses are offered through the Center. For more information regarding the Remote Sensing GIS Center, please contact Andrew J. Bruzewicz, Director, or Timothy Pangburn, Branch Chief of Remote Sensing GIS and Water Resources, at 603-646-4372 and 603-646-4296.

h. This manual represents the combined efforts of individuals from Science and Technology Corporation (STC), Dartmouth College, and USACE-ERDC-CRREL. Principal contributors include Lorin J. Amidon (STC), Emily S. Bryant (Dartmouth College), Dr. Robert L. Bolus (ERDC-CRREL), and Brian T. Tracy (ERDC-CRREL).

Chapter 2

Principles Of Remote Sensing Systems

2-1 Introduction. The principles of remote sensing are based primarily on the properties of the electromagnetic spectrum and the geometry of airborne or satellite platforms relative to their targets. This chapter provides a background on the physics of remote sensing, including discussions of energy sources, electromagnetic spectra, atmospheric effects, interactions with the target or ground surface, spectral reflectance curves, and the geometry of image acquisition.

2-2 Definition of Remote Sensing.

a. Remote sensing describes the collection of data about an object, area, or phenomenon from a distance with a device that is not in contact with the object. More commonly, the term remote sensing refers to imagery and image information derived by both airborne and satellite platforms that house sensor equipment. The data collected by the sensors are in the form of electromagnetic energy (EM). Electromagnetic energy is the energy emitted, absorbed, or reflected by objects. Electromagnetic energy is synonymous to many terms, including electromagnetic radiation, radiant energy, energy, and radiation.

b. Sensors carried by platforms are engineered to detect variations of emitted and reflected electromagnetic radiation. A simple and familiar example of a platform carrying a sensor is a camera mounted on the underside of an airplane. The airplane may be a high or low altitude platform while the camera functions as a sensor collecting data from the ground. The data in this example are reflected electromagnetic energy commonly known as visible light. Likewise, spaceborne platforms known as satellites, such as Landsat Thematic Mapper (Landsat TM) or SPOT (Satellite Pour l'Observation de la Terra), carry a variety of sensors. Similar to the camera, these sensors collect emitted and reflected electromagnetic energy, and are capable of recording radiation from the visible and other portions of the spectrum. The type of platform and sensor employed will control the image area and the detail viewed in the image, and additionally they record characteristics of objects not seen by the human eye.

c. For this manual, remote sensing is defined as the acquisition, processing, and analysis of surface and near surface data collected by airborne and satellite systems.

2-3 Basic Components of Remote Sensing.

a. The overall process of remote sensing can be broken down into five components. These components are: 1) an energy source; 2) the interaction of this energy with particles in the atmosphere; 3) subsequent interaction with the ground target; 4) energy recorded by a sensor as data; and 5) data displayed digitally for visual and numerical interpretation. This chapter examines components 1–4 in detail. Component 5 will be discussed in Chapter 5. Figure 2-1 illustrates the basic elements of airborne and satellite remote sensing systems.

b. Primary components of remote sensing are as follows:

- Electromagnetic energy is emitted from a source.
- This energy interacts with particles in the atmosphere.
- Energy interacts with surface objects.
- Energy is detected and recorded by the sensor.
- Data are displayed digitally for visual and numerical interpretation on a computer.

Figure 2-1. The satellite remote sensing process. A—Energy source or illumination (electromagnetic energy); B—radiation and the atmosphere; C—interaction with the target; D—recording of energy by the sensor; E—transmission, reception, and processing; F—interpretation and analysis; G—application. Modified from http://www.ccrs.nrcan.gc.ca/ccrs/learn/tutorials/fundam/chapter1/chapter1_1_e.html, courtesy of the Natural Resources Canada.

2-4 Component 1: Electromagnetic Energy Is Emitted From A Source.

a. *Electromagnetic Energy: Source, Measurement, and Illumination.* Remote sensing data become extremely useful when there is a clear understanding of the physical principles that govern what we are observing in the imagery. Many of these physical principles have been known and understood for decades, if not hundreds of years. For this manual, the discussion will be limited to the critical elements that contribute to our understanding of remote sensing principles. If you should need further explanation, there are numerous works that expand upon the topics presented below (see Appendix A).

b. Summary of Electromagnetic Energy. Electromagnetic energy or radiation is derived from the subatomic vibrations of matter and is measured in a quantity known as wavelength. The units of wavelength are traditionally given as micrometers (μm) or nanometers (nm). Electromagnetic energy travels through space at the speed of light and can be absorbed and reflected by objects. To understand electromagnetic energy, it is necessary to discuss the origin of radiation, which is related to the temperature of the matter from which it is emitted.

c. Temperature. The origin of all energy (electromagnetic energy or radiant energy) begins with the vibration of subatomic particles called photons (Figure 2-2). All objects at a temperature above absolute zero vibrate and therefore emit some form of electromagnetic energy. Temperature is a measurement of this vibrational energy emitted from an object. Humans are sensitive to the thermal aspects of temperature; the higher the temperature is the greater is the sensation of heat. A “hot” object emits relatively large amounts of energy. Conversely, a “cold” object emits relatively little energy.

Figure 2-2. As an electron jumps from a higher to lower energy level, shown in top figure, a photon of energy is released. The absorption of photon energy by an atom allows electrons to jump from a lower to a higher energy state.

d. Absolute Temperature Scale. The lowest possible temperature has been shown to be -273.2°C and is the basis for the absolute temperature scale. The absolute temperature scale, known as Kelvin, is adjusted by assigning -273.2°C to 0 K (“zero Kelvin”); no de-

gree sign). The Kelvin scale has the same temperature intervals as the Celsius scale, so conversion between the two scales is simply a matter of adding or subtracting 273 (Table 2-1). Because all objects with temperatures above, or higher than, zero Kelvin emit electromagnetic radiation, it is possible to collect, measure, and distinguish energy emitted from adjacent objects.

Table 2-1
Different scales used to measure object temperature. Conversion formulas are listed below.

Object	Fahrenheit (°F)	Celsius (°C)	Kelvin (K)
Absolute Zero	-459.7	-273.2	0.0
Frozen Water	32.0	0.0	273.16
Boiling Water	212.0	100.0	373.16
Sun	9981.0	5527.0	5800.0
Earth	46.4	8.0	281.0
Human body	98.6	37.0	310.0

Conversion Formulas:

Celsius to Fahrenheit: $F^{\circ} = (1.8 \times C^{\circ}) + 32$

Fahrenheit to Celsius: $C^{\circ} = (F^{\circ} - 32)/1.8$

Celsius to Kelvin: $K = C^{\circ} + 273$

Fahrenheit to Kelvin: $K = [(F^{\circ} - 32)/1.8] + 273$

Figure 2-3. Propagation of the electromagnetic and magnetic field. Waves vibrate perpendicular to the direction of motion; electric and magnetic fields are at right angle to each other. These fields travel at the speed of light.

e. Nature of Electromagnetic Waves. Electromagnetic energy travels along the path of a sinusoidal wave (Figure 2-3). This wave of energy moves at the speed of light (3.00×10^8 m/s). All emitted and reflected energy travels at this rate, including light. Electromagnetic energy has two components, the electric and magnetic fields. This energy is defined by its wavelength (λ) and frequency (ν); see below for units. These fields are in-phase, perpendicular to one another, and oscillate normal to their direction of propagation (Figure 2-3). Familiar forms of radiant energy include X-rays, ultraviolet rays, visible

light, microwaves, and radio waves. All of these waves move and behave similarly; they differ only in radiation intensity.

f. Measurement of Electromagnetic Wave Radiation.

(1) *Wavelength.* Electromagnetic waves are measured from wave crest to wave crest or conversely from trough to trough. This distance is known as wavelength (λ or "lambda"), and is expressed in units of micrometers (μm) or nanometers (nm) (Figures 2-4 and 2-5).

Figure 2-4. Wave morphology—wavelength (λ) is measured from crest-to-crest or trough-to-trough.

Figure 2-5. Long wavelengths maintain a low frequency and lower energy state relative to the short wavelengths.

(2) *Frequency.* The rate at which a wave passes a fixed point is known as the wave frequency and is denoted as ν ("nu"). The units of measurement for frequency are given as Hertz (Hz), the number of wave cycles per second (Figures 2-5 and 2-6).

Figure 2-6. Frequency (ν) refers to the number of crests of waves of the same wavelength that pass by a point (P) in each second.

(3) *Speed of electromagnetic radiation (or speed of light).* Wavelength and frequency are inversely related to one another, in other words as one increases the other decreases. Their relationship is expressed as:

$$c = \lambda \nu \quad (2-1)$$

where

$c = 3.00 \times 10^8$ m/s, the speed of light

λ = the wavelength (m)

ν = frequency (cycles/second, Hz).

This mathematical expression also indicates that wavelength (λ) and frequency (ν) are both proportional to the speed of light (c). Because the speed of light (c) is constant, radiation with a small wavelength will have a high frequency; conversely, radiation with a large wavelength will have a low frequency.

Figure 2-7. Electromagnetic spectrum displayed in meter and Hz units. Short wavelengths are shown on the left, long wavelength on the right. The visible spectrum shown in red.

g. Electromagnetic Spectrum. Electromagnetic radiation wavelengths are plotted on a logarithmic scale known as the electromagnetic spectrum. The plot typically increases in increments of powers of 10 (Figure 2-7). For convenience, regions of the electromagnetic spectrum are categorized based for the most part on methods of sensing their wavelengths. For example, the visible light range is a category spanning 0.4–0.7 μm . The

minimum and maximum of this category is based on the ability of the human eye to sense radiation energy within the 0.4- to 0.7- μm wavelength range.

(1) Though the spectrum is divided up for convenience, it is truly a continuum of increasing wavelengths with no inherent differences among the radiations of varying wavelengths. For instance, the scale in Figure 2-8 shows the color blue to be approximately in the range of 435 to 520 nm (on other scales it is divided out at 446 to 520 nm). As the wavelengths proceed in the direction of green they become increasingly less blue and more green; the boundary is somewhat arbitrarily fixed at 520 nm to indicate this gradual change from blue to green.

Figure 2-8. Visible spectrum illustrated here in color.

(2) Be aware of differences in the manner in which spectrum scales are drawn. Some authors place the long wavelengths to the right (such as those shown in this manual), while others place the longer wavelengths to the left. The scale can also be drawn on a vertical axis (Figure 2-9). Units can be depicted in meters, nanometers, micrometers, or a combination of these units. For clarity some authors add color in the visible spectrum to correspond to the appropriate wavelength.

Figure 2-9. Electromagnetic spectrum on a vertical scale.

h. Regions of the Electromagnetic Spectrum. Different regions of the electromagnetic spectrum can provide discrete information about an object. The categories of the electromagnetic spectrum represent groups of measured electromagnetic radiation with similar wavelength and frequency. Remote sensors are engineered to detect specific spectrum wavelength and frequency ranges. Most sensors operate in the visible, infrared, and microwave regions of the spectrum. The following paragraphs discuss the electromagnetic spectrum regions and their general characteristics and potential use (also see Appendix B). The spectrum regions are discussed in order of increasing wavelength and decreasing frequency.

(1) *Ultraviolet.* The ultraviolet (UV) portion of the spectrum contains radiation just beyond the violet portion of the visible wavelengths. Radiation in this range has short wavelengths (0.300 to 0.446 μm) and high frequency. UV wavelengths are used in geologic and atmospheric science applications. Materials, such as rocks and minerals, fluoresce or emit visible light in the presence of UV radiation. The fluorescence associated with natural hydrocarbon seeps is useful in monitoring oil fields at sea. In the upper at-

mosphere, ultraviolet light is greatly absorbed by ozone (O₃) and becomes an important tool in tracking changes in the ozone layer.

(2) *Visible Light.* The radiation detected by human eyes is in the spectrum range aptly named the visible spectrum. Visible radiation or light is the only portion of the spectrum that can be perceived as colors. These wavelengths span a very short portion of the spectrum, ranging from approximately 0.4 to 0.7 μm . Because of this short range, the visible portion of the spectrum is plotted on a linear scale (Figure 2-8). This linear scale allows the individual colors in the visible spectrum to be discretely depicted. The shortest visible wavelength is violet and the longest is red.

(a) The visible colors and their corresponding wavelengths are listed below (Table 2-2) in micrometers and shown in nanometers in Figure 2.8.

Table 2-2	
Wavelengths of the primary colors of the visible spectrum	
Color	Wavelength
Violet	0.4–0.446 μm
Blue	0.446–0.500 μm
Green	0.500–0.578 μm
Yellow	0.578–0.592 μm
Orange	0.592–0.620 μm
Red	0.620–0.7 μm

(b) Visible light detected by sensors depends greatly on the surface reflection characteristics of objects. Urban feature identification, soil/vegetation discrimination, ocean productivity, cloud cover, precipitation, snow, and ice cover are only a few examples of current applications that use the visible range of the electromagnetic spectrum.

(3) *Infrared.* The portion of the spectrum adjacent to the visible range is the infrared (IR) region. The infrared region, plotted logarithmically, ranges from approximately 0.7 to 100 μm , which is more than 100 times as wide as the visible portion. The infrared region is divided into two categories, the reflected IR and the emitted or thermal IR; this division is based on their radiation properties.

(a) *Reflected Infrared.* The reflected IR spans the 0.7- to 3.0- μm wavelengths. Reflected IR shares radiation properties exhibited by the visible portion and is thus used for similar purposes. Reflected IR is valuable for delineating healthy verses unhealthy or fallow vegetation, and for distinguishing among vegetation, soil, and rocks.

(b) *Thermal Infrared.* The thermal IR region represents the radiation that is emitted from the Earth's surface in the form of thermal energy. Thermal IR spans the 3.0- to 100- μm range. These wavelengths are useful for monitoring temperature variations in land, water, and ice.

(4) *Microwave.* Beyond the infrared is the microwave region, ranging on the spectrum from 1 μm to 1 m (bands are listed in Table 2-3). Microwave radiation is the longest

wavelength used for remote sensing. This region includes a broad range of wavelengths; on the short wavelength end of the range, microwaves exhibit properties similar to the thermal IR radiation, whereas the longer wavelengths maintain properties similar to those used for radio broadcasts.

Table 2-3
Wavelengths of various bands in the microwave range

Band	Frequency (MHz)	Wavelength (cm)
Ka	40,000–26,000	0.8–1.1
K	26,500–18,500	1.1–1.7
X	12,500–8000	2.4–3.8
C	8000–4000	3.8–7.5
L	2000–1000	15.0–30.0
P	1000–300	30.0–100.0

(a) Microwave remote sensing is used in the studies of meteorology, hydrology, oceans, geology, agriculture, forestry, and ice, and for topographic mapping. Because microwave emission is influenced by moisture content, it is useful for mapping soil moisture, sea ice, currents, and surface winds. Other applications include snow wetness analysis, profile measurements of atmospheric ozone and water vapor, and detection of oil slicks.

(b) For more information on spectrum regions, see Appendix B.

i. *Energy as it Relates to Wavelength, Frequency, and Temperature.* As stated above, energy can be quantified by its wavelength and frequency. It is also useful to measure the intensity exhibited by electromagnetic energy. Intensity can be described by Q and is measured in units of Joules.

(1) *Quantifying Energy.* The energy released from a radiating body in the form of a vibrating photon traveling at the speed of light can be quantified by relating the energy's wavelength with its frequency. The following equation shows the relationship between wavelength, frequency, and amount of energy in units of Joules:

$$Q = h \nu \quad (2-2)$$

Because $c = \lambda \nu$, Q also equals

$$Q = h c / \lambda$$

where

- Q = energy of a photon in Joules (J)
- h = Planck's constant (6.6×10^{-34} J s)
- c = 3.00×10^8 m/s, the speed of light
- λ = wavelength (m)
- ν = frequency (cycles/second, Hz).

The equation for energy indicates that, for long wavelengths, the amount of energy will be low, and for short wavelengths, the amount of energy will be high. For instance, blue light is on the short wavelength end of the visible spectrum (0.446 to 0.050 μm) while red is on the longer end of this range (0.620 to 0.700 μm). Blue light is a higher energy radiation than red light. The following example illustrates this point:

Example: Using $Q = h c/\lambda$, which has more energy blue or red light?

Solution: Solve for Q_{blue} (energy of blue light) and Q_{red} (energy of red light) and compare.

Calculation: $\lambda_{\text{blue}}=0.425 \mu\text{m}$, $\lambda_{\text{red}}=0.660 \mu\text{m}$ (From Table 2-2)

$$h = 6.6 \times 10^{-34} \text{ J s}$$

$$c = 3.00 \times 10^8 \text{ m/s}$$

* Don't forget to convert length μm to meters (not shown here)

Blue

$$Q_{\text{blue}} = 6.6 \times 10^{-34} \text{ J s } (3.00 \times 10^8 \text{ m/s}) / 0.425 \mu\text{m}$$

$$Q_{\text{blue}} = 4.66 \times 10^{-31} \text{ J}$$

Red

$$Q_{\text{red}} = 6.6 \times 10^{-34} \text{ J seconds } (3.00 \times 10^8 \text{ m/s}) / 0.660 \mu\text{m}$$

$$Q_{\text{red}} = 3.00 \times 10^{-31} \text{ J}$$

Answer: Because $4.66 \times 10^{-31} \text{ J}$ is greater than $3.00 \times 10^{-31} \text{ J}$ *blue* has more energy.

This explains why the blue portion of a fire is hotter than the red portions.

(2) *Implications for Remote Sensing.* The relationship between energy and wavelengths has implications for remote sensing. For example, in order for a sensor to detect low energy microwaves (which have a large λ), it will have to remain fixed over a site for a relatively long period of time, known as dwell time. Dwell time is critical for the collection of an adequate amount of radiation. Conversely, low energy microwaves can be detected by “viewing” a larger area to obtain a detectable microwave signal. The latter is typically the solution for collecting lower energy microwaves.

j. Black Body Emission. Energy emitted from an object is a function of its surface temperature (refer to Paragraph 2-4c and d). An idealized object called a black body is used to model and approximate the electromagnetic energy emitted by an object. A black body completely absorbs and re-emits all radiation incident (striking) to its surface. A black body emits electromagnetic radiation at all wavelengths if its temperature is above 0 Kelvin. The Wien and Stefan-Boltzmann Laws explain the relationship between temperature, wavelength, frequency, and intensity of energy.

(1) *Wien's Displacement Law*. In Equation 2-2 wavelength is shown to be an inverse function of energy. It is also true that wavelength is inversely related to the temperature of the source. This is explained by Wein's displacement law (Equation 2-3):

$$L_m = A/T \quad (2-3)$$

where

$$\begin{aligned} L_m &= \text{maximum wavelength} \\ A &= 2898 \mu\text{m Kelvin} \\ T &= \text{temperature Kelvin emitted from the object.} \end{aligned}$$

Using this formula (Equation 2-3), we can determine the temperature of an object by measuring the wavelength of its incoming radiation.

Example: Using $L_m = A/T$, what is the maximum wavelength emitted by a human?

Solution: Solve for L_m given T from Table 2-1

Calculation: $T = 98.6^\circ\text{C}$ or 310 K (From Table 2-1)
 $A = 2898 \mu\text{m Kelvin}$

$$L_m = 2898 \mu\text{m K}/310\text{K}$$

$$L_m = 9.3 \mu\text{m}$$

Answer: Humans emit radiation at a maximum wavelength of $9.3 \mu\text{m}$; this is well beyond what the eye is capable of seeing. Humans can see in the visible part of the electromagnetic spectrum at wavelengths of $0.4\text{--}0.7\mu\text{m}$.

(2) *The Stefan-Boltzmann Law*. The Stefan-Boltzmann Law states that the total energy radiated by a black body per volume of time is proportional to the fourth power of temperature. This can be represented by the following equation:

$$M = \sigma T^4 \quad (2-4)$$

where

$$\begin{aligned} M &= \text{radiant surface energy in watts (w)} \\ \sigma &= \text{Stefan-Boltzmann constant } (5.6697 \times 10^{-8} \text{ w/m}^2\text{K}^4) \\ T &= \text{temperature in Kelvin emitted from the object.} \end{aligned}$$

This simply means that the total energy emitted from an object rapidly increases with only slight increases in temperature. Therefore, a hotter black body emits more radiation at each wavelength than a cooler one (Figure 2-10).

Figure 2-10. Spectral intensity of different emitted temperatures. The horizontal axis is wavelength in nm and the vertical axis is spectral intensity. The vertical bars denote the peak intensity for the temperatures presented. These peaks indicate a shift toward higher energies (lower wavelengths) with increasing temperatures. Modified from <http://rst.gsfc.nasa.gov/Front/overview.html>.

(3) *Summary.* Together, the Wien and Stefan-Boltzmann Laws are powerful tools. From these equations, temperature and radiant energy can be determined from an object's emitted radiation. For example, ocean water temperature distribution can be mapped by measuring the emitted radiation; discrete temperatures over a forest canopy can be detected; and surface temperatures of distant solar system objects can be estimated.

k. The Sun and Earth as Black Bodies. The Sun's surface temperature is 5800 K; at that temperature much of the energy is radiated as visible light (Figure 2-11). We can therefore see much of the spectra emitted from the sun. Scientists speculate the human eye has evolved to take advantage of the portion of the electromagnetic spectrum most readily available (i.e., sunlight). Also, note from the figure the Earth's emitted radiation peaks between 6 to 16 μm ; to "see" these wavelengths one must use a remote sensing detector.

Figure 2-11. The Sun and Earth both emit electromagnetic radiation. The Sun's temperature is approximately 5770 Kelvin, the Earth's temperature is centered on 300 Kelvin.

1. Passive and Active Sources. The energy referred to above is classified as passive energy. Passive energy is emitted directly from a natural source. The Sun, rocks, ocean, and humans are all examples of passive sources. Remote sensing instruments are capable of collecting energy from both passive and active sources (Figure 2-1; path B). Active energy is energy generated and transmitted from the sensor itself. A familiar example of an active source is a camera with a flash. In this example visible light is emitted from a flash to illuminate an object. The reflected light from the object being photographed will return to the camera where it is recorded onto film. Similarly, active radar sensors transmit *their own* microwave energy to the surface terrain; the strength of energy returned to the sensor is recorded as representing the surface interaction. The Earth and Sun are the most common sources of energy used in remote sensing.

2-5 Component 2: Interaction of Electromagnetic Energy With Particles in the Atmosphere.

a. Atmospheric Effects. Remote sensing requires that electromagnetic radiation travel some distance through the Earth's atmosphere from the source to the sensor. Radiation from the Sun or an active sensor will initially travel through the atmosphere, strike the ground target, and pass through the atmosphere a second time before it reaches a sensor

(Figure 2-1; path B). The total distance the radiation travels in the atmosphere is called the path length. For electromagnetic radiation emitted from the Earth, the path length will be half the path length of the radiation from the sun or an active source.

(1) As radiation passes through the atmosphere, it is greatly affected by the atmospheric particles it encounters (Figure 2-12). This effect is known as atmospheric scattering and atmospheric absorption and leads to changes in intensity, direction, and wavelength size. The change the radiation experiences is a function of the atmospheric conditions, path length, composition of the particle, and the wavelength measurement relative to the diameter of the particle.

Figure 2-12. Various radiation obstacles and scatter paths. Modified from two sources, <http://orbit-net.nesdis.noaa.gov/arad/fpdt/tutorial/12-atmra.gif> and http://rst.gsfc.nasa.gov/Intro/Part2_4.html.

(2) Rayleigh scattering, Mie scattering, and nonselective scattering are three types of scatter that occur as radiation passes through the atmosphere (Figure 2-12). These types of scatter lead to the redirection and diffusion of the wavelength in addition to making the path of the radiation longer.

b. Rayleigh Scattering. Rayleigh scattering dominates when the diameter of atmospheric particles are much smaller than the incoming radiation wavelength ($\phi < \lambda$). This leads to a greater amount of short wavelength scatter owing to the small particle size of atmospheric gases. Scattering is inversely proportional to wavelength by the 4th power, or...

$$\text{Rayleigh Scatter} = 1/\lambda^4 \quad (2-5)$$

where λ is the wavelength (m). This means that short wavelengths will undergo a large amount of scatter, while large wavelengths will experience little scatter. Smaller wavelength radiation reaching the sensor will appear more diffuse.

c. *Why the sky is blue?* Rayleigh scattering accounts for the Earth's blue sky. We see predominately blue because the wavelengths in the blue region (0.446–0.500 μm) are more scattered than other spectra in the visible range. At dusk, when the sun is low in the horizon creating a longer path length, the sky appears more red and orange. The longer path length leads to an increase in Rayleigh scatter and results in the depletion of the blue wavelengths. Only the longer red and orange wavelengths will reach our eyes, hence beautiful orange and red sunsets. In contrast, our moon has no atmosphere; subsequently, there is no Rayleigh scatter. This explains why the moon's sky appears black (shadows on the moon are more black than shadows on the Earth for the same reason, see Figure 2-13).

Figure 2-13. Moon rising in the Earth's horizon (left). The Earth's atmosphere appears blue due to Rayleigh Scatter. Photo taken from the moon's surface shows the Earth rising (right). The Moon has no atmosphere, thus no atmospheric scatter. Its sky appears black. Images taken from: <http://antwrp.gsfc.nasa.gov/apod/ap001028.html>, and <http://antwrp.gsfc.nasa.gov/apod/ap001231.html>.

d. *Mie Scattering.* Mie scattering occurs when an atmospheric particle diameter is equal to the radiation's wavelength ($\phi = \lambda$). This leads to a greater amount of scatter in the long wavelength region of the spectrum. Mie scattering tends to occur in the presence of water vapor and dust and will dominate in overcast or humid conditions. This type of scattering explains the reddish hues of the sky following a forest fire or volcanic eruption.

e. *Nonselective Scattering.* Nonselective scattering dominates when the diameter of atmospheric particles (5–100 μm) is much larger than the incoming radiation wavelength ($\phi \gg \lambda$). This leads to the scatter of visible, near infrared, and mid-infrared. All these wavelengths are equally scattered and will combine to create a white appearance in the sky; this is why clouds appear white (Figure 2-14).

Figure 2-14. Non-selective scattering by larger atmospheric particles (like water droplets) affects all wavelengths, causing white clouds.

Figure 2-15. Atmospheric windows with wavelength on the x-axis and percent transmission measured in hertz on the y-axis. High transmission corresponds to an “atmospheric window,” which allows radiation to penetrate the Earth’s atmosphere. The chemical formula is given for the molecule responsible for sunlight absorption at particular wavelengths across the spectrum. Modified from http://earthobservatory.nasa.gov:81/Library/RemoteSensing/remote_04.html.

f. Atmospheric Absorption and Atmospheric Windows. Absorption of electromagnetic radiation is another mechanism at work in the atmosphere. This phenomenon occurs as molecules absorb radiant energy at various wavelengths (Figure 2-12). Ozone (O_3), carbon dioxide (CO_2), and water vapor (H_2O) are the three main atmospheric compounds that absorb radiation. Each gas absorbs radiation at a particular wavelength. To a lesser extent, oxygen (O_2) and nitrogen dioxide (NO_2) also absorb radiation (Figure 2-15). Be-

low is a summary of these three major atmospheric constituents and their significance in remote sensing.

g. The role of atmospheric compounds in the atmosphere.

(1) *Ozone.* Ozone (O₃) absorbs harmful ultraviolet radiation from the sun. Without this protective layer in the atmosphere, our skin would burn when exposed to sunlight.

(2) *Carbon Dioxide.* Carbon dioxide (CO₂) is called a greenhouse gas because it greatly absorbs thermal infrared radiation. Carbon dioxide thus serves to trap heat in the atmosphere from radiation emitted from both the Sun and the Earth.

(3) *Water vapor.* Water vapor (H₂O) in the atmosphere absorbs incoming long-wave infrared and shortwave microwave radiation (22 to 1 μm). Water vapor in the lower atmosphere varies annually from location to location. For example, the air mass above a desert would have very little water vapor to absorb energy, while the tropics would have high concentrations of water vapor (i.e., high humidity).

(4) *Summary.* Because these molecules absorb radiation in very specific regions of the spectrum, the engineering and design of spectral sensors are developed to collect wavelength data not influenced by atmospheric absorption. The areas of the spectrum that are not severely influenced by atmospheric absorption are the most useful regions, and are called atmospheric windows.

h. Summary of Atmospheric Scattering and Absorption. Together atmospheric scatter and absorption place limitations on the spectra range useful for remote sensing. Table 2-4 summarizes the causes and effects of atmospheric scattering and absorption due to atmospheric effects.

i. Spectrum Bands. By comparing the characteristics of the radiation in atmospheric windows (Figure 2-15; areas where reflectance on the y-axis is high), groups or bands of wavelengths have been shown to effectively delineate objects at or near the Earth's surface. The visible portion of the spectrum coincides with an atmospheric window, and the maximum emitted energy from the Sun. Thermal infrared energy emitted by the Earth corresponds to an atmospheric window around 10 μm, while the large window at wavelengths larger than 1 mm is associated with the microwave region (Figure 2-16).

Table 2-4
Properties of Radiation Scatter and Absorption in the Atmosphere

Atmospheric Scattering	Diameter (φ) of particle relative to incoming wavelength (λ)	Result
Rayleigh scattering	$\phi < \lambda$	Short wavelengths are scattered
Mie scattering	$\phi = \lambda$	Long wavelengths are scattered
Nonselective scattering	$\phi > \lambda$	All wavelengths are equally scattered
Absorption	No relationship	CO ₂ , H ₂ O, and O ₃ remove wavelengths

Figure 2-16. Atmospheric windows related to the emitted energy supplied by the sun and the Earth. Notice that the sun's maximum output (shown in yellow) coincides with an atmospheric window in the visible range of the spectrum. This phenomenon is important in optical remote sensing. Modified from

http://www.ccrs.nrcan.gc.ca/ccrs/learn/tutorials/fundam/chapter1/chapter1_4_e.html.

j. Geometric Effects. Random and non-random error occurs during the acquisition of radiation data. Error can be attributed to such causes as sun angle, angle of sensor, elevation of sensor, skew distortion from the Earth's rotation, and path length. Malfunctions in the sensor as it collects data and the motion of the platform are additional sources of error. As the sensor collects data, it can develop sweep irregularities that result in hundreds of meters of error. The pitch, roll, and yaw of platforms can create hundreds to thousands of meters of error, depending on the altitude and resolution of the sensor. Geometric corrections are typically applied by re-sampling an image, a process that shifts and recalculates the data. The most commonly used re-sampling techniques include the use of ground control points (see Chapter 5), applying a mathematical model, or re-sampling by nearest neighbor or cubic convolution.

k. Atmospheric and Geometric Corrections. Data correction is required for calculating reflectance values from radiance values (see Equation 2-5 below) recorded at a sensor and for reducing positional distortion caused by known sensor error. It is extremely important to make corrections when comparing one scene with another and when performing a temporal analysis. Corrected data can then be evaluated in relation to a spectral data library (see Paragraph 2-6b) to compare an object to its standard. Corrections are not necessary if objects are to be distinguished by relative comparisons within an individual scene.

l. Atmospheric Correction Techniques. Data can be corrected by re-sampling with the use of image processing software such as ERDAS Imagine or ENVI, or by the use of specialty software. In many of the image processing software packages, atmospheric correction models are included as a component of an import process. Also, data may have some corrections applied by the vendor. When acquiring data, it is important to be aware of any corrections that may have been applied to the data (see Chapter 4). Correction models can be mathematically or empirically derived.

m. Empirical Modeling Corrections. Measured or empirical data collected on the ground at the time the sensor passes overhead allows for a comparison between ground spectral reflectance measurements and sensor radiation reflectance measurements. Typical data collection includes spectral measurements of selected objects within a scene as well as a sampling of the atmospheric properties that prevailed during sensor acquisition. The empirical data are then compared with image data to interpolate an appropriate correction. Empirical corrections have many limitations, including cost, spectral equipment availability, site accessibility, and advanced preparation. It is critical to time the field spectral data collection to coincide with the same day and time the satellite collects radiation data. This requires knowledge of the satellite's path and revisit schedule. For archived data it is impossible to collect the field spectral measurements needed for developing an empirical model that will correct atmospheric error. In such a case, a mathematical model using an estimate of the field parameters must complete the correction.

n. Mathematical Modeling Corrections. Alternatively, corrections that are mathematically derived rely on estimated atmospheric parameters from the scene. These parameters include visibility, humidity, and the percent and type of aerosols present in the atmosphere. Data values or ratios are used to determine the atmospheric parameters. Subsequently a mathematical model is extracted and applied to the data for re-sampling. This type of modeling can be completed with the aid of software programs such as 6S, MODTRAN, and ATREM (see <http://atol.ucsd.edu/~pflatau/rtelib/> for a list and description of correction modeling software).

2-6 Component 3: Electromagnetic Energy Interacts with Surface and Near Surface Objects.

a. Energy Interactions with the Earth's Surface. Electromagnetic energy that reaches a target will be absorbed, transmitted, and reflected. The proportion of each depends on the composition and texture of the target's surface. Figure 2-17 illustrates these three interactions. Much of remote sensing is concerned with reflected energy.

Figure 2-17. Radiation striking a target is reflected, absorbed, or transmitted through the medium. Radiation is also emitted from ground targets.

(1) *Absorption.* Absorption occurs when radiation penetrates a surface and is incorporated into the molecular structure of the object. All objects absorb incoming incident radiation to some degree. Absorbed radiation can later be emitted back to the atmosphere. Emitted radiation is useful in thermal studies, but will not be discussed in detail in this work (see Lillisand and Keifer [1994] *Remote Sensing and Image Interpretation* for information on emitted energy).

(2) *Transmission.* Transmission occurs when radiation passes through material and exits the other side of the object. Transmission plays a minor role in the energy's interaction with the target. This is attributable to the tendency for radiation to be absorbed before it is entirely transmitted. Transmission is a function of the properties of the object.

(3) *Reflection.* Reflection occurs when radiation is neither absorbed nor transmitted. The reflection of the energy depends on the properties of the object and surface roughness relative to the wavelength of the incident radiation. Differences in surface properties allow the distinction of one object from another.

(a) Absorption, transmission, and reflection are related to one another by

$$E_I = E_A + E_T + E_R \quad (2-6)$$

where

- E_I = incident energy striking an object
- E_A = absorbed radiation
- E_T = transmitted energy
- E_R = reflected energy.

(b) The amount of each interaction will be a function of the incoming wavelength, the composition of the material, and the smoothness of the surface.

(4) *Reflectance of Radiation.* Reflectance is simply a measurement of the percentage of incoming or incident energy that a surface reflects

$$\text{Reflectance} = \text{Reflected energy} / \text{Incident energy} \quad (2-7)$$

where incident energy is the amount of incoming radiant energy and reflected energy is the amount of energy bouncing off the object. Or from equation 2-5:

$$E_I = E_A + E_T + E_R$$

$$\text{Reflectance} = E_R / E_I \quad (2-8)$$

Reflectance is a fixed characteristic of an object. Surface features can be distinguished by comparing the reflectance of different objects at each wavelength. Reflectance comparisons rely on the unchanging proportion of reflected energy relative to the sum of incoming energy. This permits the distinction of objects regardless of the amount of incident energy. Unique objects reflect differently, while similar objects only reflect differently if there has been a physical or chemical change. **Note:** reflectance is not the same as reflection.

Specular and diffuse reflection

The nature of reflectance is controlled by the wavelength of the radiation relative to the surface texture. Surface texture is defined by the roughness or bumpiness of the surface relative to the wavelength. Objects display a range of reflectance from diffuse to specular. Specular reflectance is a mirror-like reflection, which occurs when an object with a smooth surface reflects in one direction. The incoming radiation will reflect off a surface at the same angle of incidence (Figure 2-18). Diffuse or Lambertian reflectance reflects in all directions owing to a rough surface. This type of reflectance gives the most information about an object.

Figure 2-18. Specular reflection or mirror-like reflection (left) and diffuse reflection (right).

(5) *Spectral Radiance*. As reflected energy radiates away from an object, it moves in a hemi-spherical path. The sensor measures only a small portion of the reflected radiation—the portion along the path between the object and the sensor (Figure 2-19). This measured radiance is known as the spectral radiance (Equation 2-9).

$$I = \text{Reflected radiance} + \text{Emitted radiance}$$

2-9

where I = radiant intensity in watts per steradian (W sr^{-1}). (Steradian is the unit of cone angle, abbreviated sr, 1 sr equals 4π . See the following for more details on steradian.)

http://whatis.techtarget.com/definition/0%2C%2Csid9_gci528813%2C00.html

Figure 2-19. Diffuse reflection of radiation from a single target point. Radiation moves outward in a hemispherical path. Notice the sensor only samples radiation from a single vector. Modified after http://rst.gsfc.nasa.gov/Intro/Part2_3html.html.

(6) *Summary.* Spectral radiance is the amount of energy received at the sensor per time, per area, in the direction of the sensor (measured in steradian), and it is measured per wavelength. The sensor therefore measures the fraction of reflectance for a given area/time for every wavelength as well as the emitted. Reflected and emitted radiance is calculated by the integration of energy over the reflected hemisphere resulting from diffuse reflection (see <http://rsd.gsfc.nasa.gov/goes/text/reflectance.pdf> for details on this complex calculation). Reflected radiance is orders of magnitude greater than emitted radiance. The following paragraphs, therefore, focus on reflected radiance.

b. Spectral Reflectance Curves.

(1) Background.

(a) Remote sensing consists of making spectral measurements over space: how much of what “color” of light is coming from what place on the ground. One thing that a remote sensing applications scientist hopes for, but which is not always true, is that surface features of interest will have different colors so that they will be distinct in remote sensing data.

(b) A surface feature’s color can be characterized by the *percentage* of incoming electromagnetic energy (illumination) it reflects at each wavelength across the electromagnetic spectrum. This is its spectral reflectance curve or “spectral signature”; it is an unchanging property of the material. For example, an object such as a leaf may reflect 3% of incoming blue light, 10% of green light and 3% of red light. The amount of light it reflects depends on the amount and wavelength of incoming illumination, but the percents are constant. Unfortunately, remote sensing instruments do not record reflectance directly, rather radiance, which is the *amount* (not the percent) of electromagnetic energy received in selected wavelength bands. A change in illumination, more or less intense sun for instance, will change the radiance. Spectral signatures are often represented as plots or graphs, with wavelength on the horizontal axis, and the reflectance on the vertical axis (Figure 2-20 provides a spectral signature for snow).

(2) *Important Reflectance Curves and Critical Spectral Regions.* While there are too many surface types to memorize all their spectral signatures, it is helpful to be familiar with the basic spectral characteristics of green vegetation, soil, and water. This in turn helps determine which regions of the spectrum are most important for distinguishing these surface types.

(3) *Spectral Reflectance of Green Vegetation.* Reflectance of green vegetation (Figure 2-21) is low in the visible portion of the spectrum owing to chlorophyll absorption, high in the near IR due to the cell structure of the plant, and lower again in the shortwave IR due to water in the cells. Within the visible portion of the spectrum, there is a local reflectance peak in the green (0.55 μm) between the blue (0.45 μm) and red (0.68 μm) chlorophyll absorption valleys (Samson, 2000; Lillesand and Kiefer, 1994).

Figure 2-20. Spectral reflectance of snow. Graph developed for Prospect (2002 and 2003) using Aster Spectral Library (<http://speclib.jpl.nasa.gov/>) data

Figure 2-21. Spectral reflectance of healthy vegetation. Graph developed for Prospect (2002 and 2003) using Aster Spectral Library (<http://speclib.jpl.nasa.gov/>) data

(4) *Spectral Reflectance of Soil.* Soil reflectance (Figure 2-22) typically increases with wavelength in the visible portion of the spectrum and then stays relatively constant in the near-IR and shortwave IR, with some local dips due to water absorption at 1.4 and 1.9 μm and due to clay absorption at 1.4 and 2.2 μm (Lillesand and Kiefer, 1994).

Figure 2-22. Spectral reflectance of one variety of soil. Graph developed for Prospect (2002 and 2003) using Aster Spectral Library (<http://speclib.jpl.nasa.gov/>) data

(5) *Spectral Reflectance of Water.* Spectral reflectance of clear water (Figure 2-23) is low in all portions of the spectrum. Reflectance increases in the visible portion when materials are suspended in the water (Lillesand and Kiefer, 1994).

Figure 2-23. Spectral reflectance of water. Graph developed for Prospect (2002 and 2003) using Aster Spectral Library (<http://speclib.jpl.nasa.gov/>) data

(6) *Critical Spectral Regions.* The spectral regions that will be most useful in a remote sensing application depend on the spectral signatures of the surface features to be distinguished. The figure below (Figure 2-24) shows that the visible blue region is not very useful for separating vegetation, soil, and water surface types, since all three have similar reflectance, but visible red wavelengths separate soil and vegetation. In the near-IR (refers to 0.7 to 2.5 μm), all three types are distinct, with vegetation high, soil intermediate, and water low in reflectance. In the shortwave IR, water is distinctly low, while vegetation and soil exchange positions across the spectral region. When spectral signatures cross, the spectral regions on either side of the intersection are especially useful. For instance, green vegetation and soil signatures cross at about 0.7 μm , so the 0.6- (visible red) and 0.8- μm and larger wavelengths (near IR) regions are of particular interest in separating these types. In general, vegetation studies include near IR and visible red data, water vs. land distinction include near IR or SW IR. Water quality studies might include the visible portion of the spectrum to detect suspended materials.

Figure 2-24. Spectral reflectance of grass, soil, water, and snow. Graph developed for Prospect (2002 and 2003) using Aster Spectral Library (<http://speclib.jpl.nasa.gov/>) data

(7) *Spectral Libraries.* As noted above, detailed spectral signatures of known materials are useful in determining whether and in what spectral regions surface features are distinct. Spectral reflectance curves for many materials (especially minerals) are available in existing reference archives (spectral libraries). Data in spectral libraries are gathered under controlled conditions, quality checked, and documented. Since these are re-

flectance curves, and reflectance is theoretically an unvarying property of a material, the spectra in the spectral libraries should match those of the same materials at other times or places.

(a) If data in spectral libraries are not appropriate, reflectance curves can be acquired using a spectrometer. The instrument is aimed at a known target and records the radiance reflected from the target over a fixed range of the spectrum (the 0.4- to 2.5- μm range is relatively common). The instrument must also measure the radiance coming in to the target, so that the reflected radiance can be divided by incoming radiance at each wavelength to determine spectral reflectance of the target. Given the time and expense of gathering spectra data, it is best to check spectral libraries first.

(b) Two major spectral libraries available on the internet (where spectra can be downloaded and processed locally if needed) include:

- US Geological Survey Digital Spectral Library (Clark et al. 1993)

<http://speclab.cr.usgs.gov/spectral-lib.html>

“Researchers at the Spectroscopy lab have measured the spectral reflectance of hundreds of materials in the lab and have compiled a spectral library. The libraries are used as references for material identification in remote sensing images.”

- ASTER Spectral Library (Jet Propulsion Laboratory, 1999)

<http://speclib.jpl.nasa.gov/>

“Welcome to the ASTER spectral library, a compilation of almost 2000 spectra of natural and man made materials.”

(c) The ASTER spectral library includes data from three other spectral libraries: the Johns Hopkins University (JHU) Spectral Library, the Jet Propulsion Laboratory (JPL) Spectral Library, and the United States Geological Survey (USGS—Reston) Spectral Library.”

(8) *Real Life and Spectral Signatures.* Knowledge of spectral reflectance curves is useful if you are searching a remote sensing image for a particular material, or if you want to identify what material a particular pixel represents. Before comparing image data with spectral library reflectance curves, however, you must be aware of several things.

(a) Image data, which often measure radiance above the atmosphere, may have to be corrected for atmospheric effects and converted to reflectance.

(b) Spectral reflectance curves, which typically have hundreds or thousands of spectral bands, may have to be resampled to match the spectral bands of the remote sensing image (typically a few to a couple of hundred).

(c) There is spectral variance within a surface type that a single spectral library reflectance curve does not show. For instance, the Figure 2-25 below shows spectra for a number of different soil types. Before depending on small spectral distinctions to separate

surface types, a note of caution is required: make sure that differences within a type do not drown out the differences between types.

(d) While spectral libraries have known targets that are “pure types,” a pixel in a remote sensing image very often includes a mixture of pure types: along edges of types (e.g., water and land along a shoreline), or interspersed within a type (e.g., shadows in a tree canopy, or soil background behind an agricultural crop).

Figure 2-25. Reflectance spectra of five soil types: A—soils having > 2% organic matter content (OMC) and fine texture; B— soils having < 2% OMC and low iron content; C—soils having < 2% OMC and medium iron content; D—soils having > 2% OMC, and coarse texture; and E— soil having fine texture and high iron-oxide content (> 4%).

2-7 Component 4: Energy is Detected and Recorded by the Sensor. Earlier paragraphs of this chapter explored the nature of emitted and reflected energy and the interactions that influence the resultant radiation as it traverses from source to target to sensor. This paragraph will examine the steps necessary to transfer radiation data from the satellite to the ground and the subsequent conversion of the data to a useable form for display on a computer.

a. Conversion of the Radiation to Data. Data collected at a sensor are converted from a continuous analog to a digital number. This is a necessary conversion, as electromagnetic waves arrive at the sensor as a continuous stream of radiation. The incoming radiation is sampled at regular time intervals and assigned a value (Figure 2-26). The value given to the data is based on the use of a 6-, 7-, 8-, 9-, or 10-bit binary computer coding scale; powers of 2 play an important role in this system. Using this coding allows a computer to store and display the data. The computer translates the sequence of binary numbers, given as ones and zeros, into a set of instructions with only two possible outcomes (1 or 0, meaning “on” or “off”). The binary scale that is chosen (i.e., 8 bit data) will depend on the level of brightness that the radiation exhibits. The brightness level is determined by measuring the voltage of the incoming energy. Below in Table 2-5 is a list of select bit integer binary scales and their corresponding number of brightness levels. The ranges are derived by exponentially raising the base of 2 by the number of bits.

Figure 2-26. Diagram illustrates the digital sampling of continuous analog voltage data. The DN values above the curve represent the digital output values for that line segment.

Table 2-5
Digital number value ranges for various bit data

Number of bits	Exponent of 2	Digital Number (DN)	Value Range
6	2^6	64	0–63
8	2^8	256	0–255
10	2^{10}	1024	0–1023
16	2^{16}	65536	0–65535

b. *Diversion on Data Type.* Digital number values for raw remote sensing data are usually integers. Occasionally, data can be expressed as a decimal. The most popular code for representing real numbers (a number that contains a fraction, i.e., 0.5, which is one-half) is called the IEEE (Institute of Electrical and Electronics Engineers, pronounced I-triple-E) Floating-Point Standard. ASCII text (American Standard Code for Information Interchange; pronounced *ask-ee*) is another alternative computing value sys-

tem. This system is used for text data. You may need to be aware of the type of data used in an image, particularly when determining the digital number in a pixel.

c. Transferring the Data from the Satellite to the Ground. The transfer of data stored in the sensor from the satellite to the user is similar to the transmission of more familiar signals, such as radio and television broadcasts and cellular phone conversations. Everything we see and hear, whether it is a TV program with audio or a satellite image, originates as a form of electromagnetic radiation. To transfer satellite data from the sensor to a location on the ground, the radiation is coded (described in Paragraph 2-7a) and attached to a signal. The signal is generally a high frequency electromagnetic wave that travels at the speed of light. The data are instantaneously transferred and detected with the use of an appropriate antenna and receiver.

d. Satellite Receiving Stations.

(1) Satellite receiving stations are positioned throughout the world. Each satellite program has its own fleet of receiving stations with a limited range from which it can pick up the satellite signal. For an example of locations and coverage of SPOT receiving stations go to

<http://www.spotimage.fr/home/system/introexp/station/welcome.htm>.

(2) Satellites can only transmit data when in range of a receiving station. When outside of a receiving range, satellites will store data until they fly within range of the next receiving station. Some satellite receiving stations are mobile and can be placed on airplanes for swift deployment. A mobile receiving station is extremely valuable for the immediate acquisition of data relating to an emergency situation (flooding, forest fire, military strikes).

e. Data is Prepared for User. Once transmitted the carrier signal is filtered from the data, which are decoded and recorded onto a high-density digital tape (HDDT) or a CD-ROM, and in some cases transferred via file transfer protocol (FTP). The data can then undergo geometric and radiometric preprocessing, generally by the vendor. The data are subsequently recorded onto tape or CD compatible for a computer.

f. Hardware and Software Requirements. The hardware and software needed for satellite image analysis will depend on the type of data to be processed. A number of free image processing software programs are available and can be downloaded from the internet. Some vendors provide a free trial or free tutorials. Highly sophisticated and powerful software packages are also available for purchase. These packages require robust hardware systems to sustain extended use. Software and hardware must be capable of managing the requirements of a variety of data formats and file sizes. A single satellite image file can be 300 MB prior to enhancement processing. Once processed and enhanced, the resulting data files will be large and will require storage for continued analysis. Because of the size of these files, software and hardware can be pushed to its limits. Regularly save and back up your data files as software and hardware pushed to its limits can crash,

losing valuable information. Be sure to properly match your software requirements with appropriate hardware capabilities.

g. Turning Digital Data into Images.

(1) Satellite data can be displayed as an image on a computer monitor by an array of pixels, or picture elements, containing digital numbers. The composition of the image is simply a grid of continuous pixels, known as a raster image (Figure 2-27). The digital number (DN) of a pixel is the result of the spatial, spectral, and radiometric averaging of reflected/emitted radiation from a given area of ground cover (see below for information on spatial, spectral, and radiometric resolution). The DN of a pixel is therefore the average radiance of the surface area the pixel represents.

Figure 2-27. Figure illustrates the collection of raster data. Black grid (left) shows what area on the ground is covered by each pixel in the image (right). A sensor measures the average spectrum from each pixel, recording the photons coming in from that area. ASTER data of Lake Kissimmee, Florida, acquired 2001-08-18. Image developed for Prospect (2002 and 2003).

(2) The value given to the DN is based on the brightness value of the radiation (see explanation above and Figure 2-28). For most radiation, an 8-bit scale is used that corresponds to a value range of 0–255 (Table 2-4). This means that 256 levels of brightness (DN values are sometimes referred to as brightness values— B_v) can be displayed, each representing the intensity of the reflected/emitted radiation. On the image this translates to varying shades of grays. A pixel with a brightness value of zero ($B_v = 0$) will appear black; a pixel with a B_v of 255 will appear white (Figure 2-29). All brightness values in the range of $B_v = 1$ to 254 will appear as increasingly brighter shades of gray. In Figure 2-30, the dark regions represent water-dominated pixels, which have low reflectance/ B_v , while the bright areas are developed land (agricultural and forested), which has high reflectance.

Figure 2-28. Brightness levels at different radiometric resolutions. Image developed for USACE Prospect #196 (2002).

Figure 2-29. Raster array and accompanying digital number (DN) values for a single band image. Dark pixels have low DN values while bright pixels have high values. Modified from Natural Resources Canada image

http://www.ccrs.nrcan.gc.ca/ccrs/learn/tutorials/fundam/chapter1/chapter1_7_e.html.

Figure 2-30. Landsat MSS band 5 data of San Francisco, California. The black pixels represent water; the various levels of gray to bright pixels represent different vegetation and ground cover types across the landscape. Image taken from http://sfbay.wr.usgs.gov/access/change_detect/Satellite/Images2.html.

h. Converting Digital Numbers to Radiance. Conversion of a digital number to its corresponding radiance is necessary when comparing images from different satellite sensors or from different times. Each satellite sensor has its own calibration parameter, which is based on the use of a linear equation that relates the minimum and maximum radiation brightness. Each spectrum band (see Paragraph 2-7*i*) also has its own radiation minimum and maximum.

(1) Information pertaining to the minimum and maximum brightness ($L_{\min}$ and $L_{\max}$ respectively) is usually found in the metadata (see Chapter 5). The equation for determining radiance from the digital number is:

$$L = (L_{\max} - L_{\min}) / 255 \times DN + L_{\min} \quad (2-10)$$

where

- L = radiance expressed in $\text{Wm}^{-2} \text{sr}^{-1}$
- $L_{\min}$ = spectral radiance corresponding to the minimum digital number
- $L_{\max}$ = spectral radiance corresponding to the maximum digital number
- DN = digital number given a value based on the bit scale used.

(2) This conversion can also be used to enhance the visual appearance of an image by reassigning the DN values so they span the full gray scale range (see Paragraph 5-20).

i. Spectral Bands.

(1) Sensors collect wavelength data in bands. A number or a letter is typically assigned to a band. For instance, radiation that spans 0.45 to 0.52 μm is designated as band 1 for Landsat 7 data; in the microwave region radiation spanning 15 to 30 cm is termed the L-band. Not all bands are created equally. Landsat band 1 (B1) does not represent the same wavelengths as SPOT's B1.

(2) Band numbers are not the same as sensor numbers. For instance Landsat 4 *does not* refer to band 4. It instead refers to the fourth satellite sensor placed into orbit by the Landsat program. This can be confusing, as each satellite program has a fleet of satellites (in or out of commission at different times), and each satellite program will define bands differently. Two different satellites from the same program may even be collecting radiation at a slightly difference wavelength range for the same band (Table 2-6). It is, therefore, important to know which satellite program and which sensor collected the data.

Table 2-6
Landsat Satellites and Sensors

The following table lists Landsat satellites 1-7, and provides band information and pixel size. The band numbers for one sensor does not necessarily imply the same wavelength range. For example, notice that band 4 in Landsat 1-2 and 3 differ from the band 4 in Landsat 4-5 and Landsat 7. Source: http://landsat.gsfc.nasa.gov/guides/LANDSAT-7_dataset.html#8.

Satellite	Sensor	Band number	Band wavelengths	Pixel Size
Landsats 1-2	RBV	1)	0.45 to 0.57	80
		2)	0.58 to 0.68	80
		3)	0.70 to 0.83	80
	MSS	4)	0.5 to 0.6	79
		5)	0.6 to 0.7	79
		6)	0.7 to 0.8	79
		7)	0.8 to 1.1	79
Landsat 3	RBV	1)	0.45 to 0.52	40

Satellite	Sensor	Band number	Band wavelengths	Pixel Size
	MSS	4)	0.5 to 0.6	79
		5)	0.6 to 0.7	79
		6)	0.7 to 0.8	79
		7)	0.8 to 1.1	79
		8)	10.4 to 12.6	240
Landsat 4-5	MSS	4)	0.5 to 0.6	82
		5)	0.6 to 0.7	82
		6)	0.7 to 0.8	82
		7)	0.8 to 1.1	82
	TM	1)	0.45 to 0.52	30
		2)	0.52 to 0.60	30
		3)	0.63 to 0.69	30
		4)	0.76 to 0.90	30
		5)	1.55 to 1.75	30
		6)	10.4 to 12.5	120
		7)	2.08 to 2.35	30
	ETM	1)	0.45 to 0.52	30
		2)	0.52 to 0.60	30
		3)	0.63 to 0.69	30
		4)	0.76 to 0.90	30
		5)	1.55 to 1.75	30
		6)	10.4 to 12.5	150
		7)	2.08 to 2.35	30
	PAN	4)	0.50 to 0.90	15

j. Color in the Image. Computers are capable of imaging three primary colors: red, green, and blue (RGB). This is different from the color system used by printers, which uses magenta, cyan, yellow, and black. The color systems are unique because of differences in the nature of the application of the color. In the case of color on a computer monitor, the monitor is black and the color is projected (called additive color) onto the screen. Print processes require the application of color to paper. This is known as a subtractive process owing to the removal of color by other pigments. For example, when white light that contains all the visible wavelengths hits a poster with an image of a yellow flower, the yellow pigment will remove the blue and green and will reflect yellow. Hence, the process is termed subtractive. The different color systems (additive vs. subtractive) account for the dissimilarities in color between a computer image and the corresponding printed image.

(1) Similar to the gray scale, color can also be displayed as an 8-bit image with 256 levels of brightness. Dark pixels have low values and will appear black with some color, while bright pixels will contain high values and will contain 100% of the designated color. In Figure 2-31, the 7 bands of a Landsat image are separated to show the varying DNs for each band.

Figure 2-31. Individual DNs can be identified in each spectral band of an image. In this example the seven bands of a subset from a Landsat image are displayed. Image developed for Prospect (2002 and 2003).

(2) When displaying an image on a computer monitor, the software allows a user to assign a band to a particular color (this is termed as “loading the band”). Because there are merely three possible colors (red, green, and blue) only three bands of spectra can be displayed at a time. The possible band choices coupled with the three-color combinations creates a seemingly endless number of possible color display choices.

(3) The optimal band choice for display will depend of the spectral information needed (see Paragraph 2-6b(7)). The color you designate for each band is somewhat arbitrary, though preferences and standards do exist. For example, a typical color/band designation of red/green/blue in bands 3/2/1 of Landsat displays the imagery as true-color. These three bands are all in the visible part of the spectrum, and the imagery appears as we see it with our eyes (Figure 2-32a). In Figure 2-32b, band 4 (B4) is displayed in the red (called “red-gun” or “red-plane”) layer of the bands 4/3/2, and vegetation in the agricultural fields appear red due to the infrared location on the spectrum. In Figure 2-32c, band 4 (B4) is displayed as green. Green is a logical choice for band 4 as it represents the wavelengths reflected by vegetation.

a. The true color image appears with these bands in the visible part of the spectrum.

b. Using the near infra-red (NIR) band (4) in the red gun, healthy vegetation appears red in the imagery.

c. Moving the NIR band into the green gun and adding band 5 to the red gun changes the vegetation to green.

Figure 2-32. Three band combinations of Landsat imagery of 3/2/1, 4/3/2, and 5/4/3 in the RGB. Images developed for Prospect (2002 and 2003).

k. Interpreting the Image. When interpreting the brightness of a gray scale image (Figure 2-33), the brightness simply represents the amount of reflectance. For bright pixels the reflectance is high, while dark pixels represent areas of low reflectance. By example, in a gray scale display of Landsat 7 band 4, the brightest pixels represent areas where there is a high reflectance in the wavelength range of 0.76 to 0.90 μm . This can be interpreted to indicate the presence of healthy vegetation (lawns and golf courses).

(1) A color composite can be somewhat difficult to interpret owing to the mixing of color. Similar to gray scale, the bright regions have high reflectance, and dark areas have low reflectance. The interpretation becomes more difficult when we combine different bands of data to produce what is known as false-color composites (Figure 2-33).

(2) White and black are the end members of the band color mixing. White pixels in a color composite represent areas where reflectance is high in all three of the bands displayed. White is produced when 100% of each color (red, green, and blue) are mixed in equal proportions. Black pixels are areas where there is an absence of color due to the low DN or reflectance. The remaining color variations represent the mixing of three band DNs. A magenta pixel is one that contains equal portions of blue and red, while lacking green. Yellow pixels are those that are high in reflectance for the bands in the green and red planes. (Go to Appendix C for a paper model of the color cube/space.)

a

b

Landsat TM bands 4, 3, 2 (RGB) image, a false color composite, highlights vegetation in red. Images are taken from http://landsat.gsfc.nasa.gov/data/Browse/Comparisons/L7_BandComparison.html.

l. Data Resolution. A major consideration when choosing a sensor type is the definition of resolution capabilities. “Resolution” in remote sensing refers to the ability of a sensor to distinguish or resolve objects that are physically near or spectrally similar to other adjacent objects. The term high or fine resolution suggests that there is a large degree of distinction in the resolution. High resolution will allow a user to distinguish small, adjacent targets. Low or coarse resolution indicates a broader averaging of radiation over a larger area (on the ground or spectrally). Objects and their boundaries will be difficult to pinpoint in images with coarse resolution. The four types of resolution in remote sensing include spatial, spectral, radiometric, and temporal.

(1) *Spatial Resolution.*

(a) An increase in spatial resolution corresponds to an increase in the ability to resolve one feature physically from another. It is controlled by the geometry and power of the sensor system and is a function of sensor altitude, detector size, focal size, and system configuration.

(b) Spatial resolution is best described by the size of an image pixel. A pixel is a two-dimensional square-shaped picture element displayed on a computer. The dimensions on the ground (measured in meters or kilometers) projected in the instantaneous field of view (IFOV) will determine the ratio of the pixel size to ground coverage. As an example, for a SPOT image with 20- ×20-m pixels, one pixel in the digital image is equivalent to 20 m square on the ground. To gauge the resolution needed to discern an object, the spatial resolution should be half the size of the feature of interest. For example, if a project requires the discernment of individual tree, the spatial resolution should be a minimum of 15 m. If you need to know the percent of timber stands versus clearcuts, a resolution of 30 m will be sufficient.

Table 2-7
Minimum image resolution required for various sized objects.

Resolution (m)	Feature Object (m)
0.5	1.0
1.0	2.0
1.5	3.0
2.0	4.0
2.5	5.0
5.0	10.0
10.0	20.0
15.0	30.0
20.0	40.0
25.0	50.0

(2) *Spectral Resolution.* Spectral resolution is the size and number of wavelengths, intervals, or divisions of the spectrum that a system is able to detect. Fine spectral resolution generally means that it is possible to resolve a large number of similarly sized wavelengths, as well as to detect radiation from a variety of regions of the spectrum. A

coarse resolution refers to large groupings of wavelengths and tends to be limited in the frequency range.

(3) *Radiometric Resolution.* Radiometric resolution is a detector's ability to distinguish differences in the strength of emitted or reflected electromagnetic radiation. A high radiometric resolution allows for the distinction between subtle differences in signal strength.

(4) *Temporal Resolution.*

(a) Temporal resolution refers to the frequency of data collection. Data collected on different dates allows for a comparison of surface features through time. If a project requires an assessment of change, or change detection, it is important to know: 1) how many data sets already exist for the site; 2) how far back in time the data set ranges; and 3) how frequently the satellite returns to acquire the same location.

(b) Most satellite platforms will pass over the same spot at regular intervals that range from days to weeks, depending on their orbit and spatial resolution (see Chapter 3). A few examples of projects that require change detection are the growth of crops, deforestation, sediment accumulation in estuaries, and urban development.

(5) *Determine the Appropriate Resolution for the Project.* Increasing resolution tends to lead to more accurate and useful information; however, this is not true for every project. The downside to increased resolution is the need for increased storage space and more powerful hardware and software. High-resolution satellite imagery may not be the best choice when all that is needed is good quality aerial photographs. It is, therefore, important to determine the minimum resolution requirements needed to accomplish a given task from the outset. This may save both time and funds.

2-8 Aerial Photography. A traditional form of mapping and surface analysis by remote sensing is the use of aerial photographs. Low altitude aerial photographs have been in use since the Civil War, when cameras mounted on balloons surveyed battlefields. Today, they provide a vast amount of surface detail from a low to high altitude, vertical perspective. Because these photographs have been collected for a longer period of time than satellite images, they allow for greater temporal monitoring of spatial changes. Roads, buildings, farmlands, and lakes are easily identifiable and, with experience, surface terrain, rock bodies, and structural faults can be identified and mapped. In the field, photographs can aid in precisely locating target sites on a map.

a. Aerial photographs record objects in the visible and near infrared and come in a variety of types and scales. Photos are available in black and white, natural color, false color infrared, and low to high resolution.

b. Resolution in aerial photographs is defined as the resolvable difference between adjacent line segments. Large-scale aerial photographs maintain a fine resolution that

allows users to isolate small objects such as individual trees. Photographs obtained at high altitudes produce a small-scale, which gives a broader view of surface features.

c. In addition to the actual print or digital image, aerial photographs typically include information pertaining to the photo acquisition. This information ideally includes the date, flight, exposure, origin/focus, scale, altitude, fiducial marks, and commissioner (Figure 2-34). If the scale is not documented on the photo, it can be determined by taking the ratio of the distance of two objects measured on the photo vs. the distance of the same two objects calculated from measurements taken from a map.

$$\text{Photo scale} = \text{photo distance/ground distance} = d/D \quad (2-11)$$

Figure 2-34. Aerial photograph of a predominately agricultural area near Modesto, California. Notice the ancillary data located on the upper and right side margins. These data provide information regarding the location and acquisition of the photo.

d. The measurement is best taken from one end of the photo to the other, passing through the center (because error in the image increases away from the focus point). For precision, it is best to average a number of ratios from across the image.

e. Photos are interpreted by recognizing various elements in a photo by the distinction of tone, texture, size, shape, pattern, shadow, site, and association. For instance, airport landing strips can look like roads, but their large widths, multiple intersections at small angles, and the positioning of airport hangers and other buildings allow the interpreter to correctly identify these “roads” as a special use area.

f. Aerial-photos are shot in a sequence with 60% overlap; this creates a stereo view when two photos are viewed simultaneously. Stereoscopic viewing geometrically corrects photos by eliminating errors attributable to camera tilt and terrain relief. Images are most easily seen in stereo by viewing them through a stereoscope. With practice it is possible to see in stereo without the stereoscope. This view will produce a three-dimensional image, allowing you to see topographic relief and resistant vs. recessive rock types.

g. To maintain accuracy it is important to correlate objects seen in the image with the actual object in the field. This verification is known as ground truth. Without ground truth you may not be able to differentiate two similarly toned objects. For instance, two very different but recessive geologic units could be mistakenly grouped together. Ground truth will also establish the level of accuracy that can be attributed to the maps created based solely on photo interpretations.

h. For information on aerial photograph acquisition, see Chapter 4. Chapter 5 presents a discussion on the digital display and use of aerial photos in image processing.

2-9 Brief History of Remote Sensing. Remote sensing technologies have been built upon by the work of researchers from a variety of disciplines. One must look further than 100 years ago to understand the foundations of this technology. For a timeline history of the development of remote sensing see http://rst.gsfc.nasa.gov/Intro/Part2_8.html. The chronology shows that remote sensing has matured rapidly since the 1970s. This advancement has been driven by both the military and commercial sectors in an effort to effectively model and monitor Earth processes. For brevity, this overview focuses on camera use in remote sensing followed by the development of two NASA programs and France’s SPOT system. To learn more about the development of remote sensing and details of other satellite programs see <http://rst.gsfc.nasa.gov/Front/tofc.html>.

a. *The Camera.* The concept of imaging the Earth’s surface has its roots in the development of the camera, a black box housing light sensitive film. A small aperture allows light reflected from objects to travel into the black box. The light then “exposes” film, positioned in the interior, by activating a chemical emulsion on the film surface. After exposure, the film negative (bright and dark are reversed) can be used to produce a positive print or a visual image of a scene.

b. Aerial Photography. The idea of mounting a camera on platforms above the ground for a “birds-eye” view came about in the mid-1800s. In the 1800’s there were few objects that flew or hovered above ground. During the US Civil War, cameras were mounted on balloons to survey battlefield sites. Later, pigeons carrying cameras were employed (<http://www2.oneonta.edu/~baumanpr/ncge/rstf.htm>), a platform with obvious disadvantages. The use of balloons and other platforms created geometric problems that were eventually solved by the development of a gyro-stabilized camera mounted on a rocket. This gyro-stabilizer was created by the German scientist Maul and was launched in 1912.

c. First Satellites. The world’s first artificial satellite, Sputnik 1, was launched on 4 October 1957 by the Soviet Union. It was not until NASA’s meteorological satellite TIROS –1 was launched that the first satellite images were produced (<http://www.earth.nasa.gov/history/tiros/tiros1.html>). Working on the same principles as the camera, satellite sensors collect reflected radiation in a range of spectra and store the data for eventual image processing (see above, this chapter).

d. NASA’s First Weather Satellites. NASA’s first satellite missions involved study of the Earth’s weather patterns. TIROS (Television Infrared Operational Satellite) missions launched 10 experimental satellites in the early 1960’s in an effort to prepare for a permanent weather bureau satellite system known as TOS (TIROS Operating System). TIROS-N (next generation) satellites currently monitor global weather and variations in the Earth’s atmosphere. The goal of TIROS-N is to acquire high resolution, diurnal data that includes vertical profile measurements of temperature and moisture.

e. Landsat Program. The 1970’s brought the introduction of the Landsat series with the launching of ERTS-1 (also known as Landsat 1) by NASA. The Landsat program was the first attempt to image whole earth resources, including terrestrial (land based) and marine resources. Images from the Landsat series allowed for detailed mapping of land-masses on a regional and continental scale.

(1) The Landsat imagery continues to provide a wide variety of information that is highly useful for identifying and monitoring resources, such as fresh water, timberland, and minerals. Landsat imagery is also used to assess hazards such as floods, droughts, forest fire, and pollution. Geographers have used Landsat images to map previously unknown mountain ranges in Antarctica and to map changes in coastlines in remote areas.

(2) A notable event in the history of the Landsat program was the addition of TM (Thematic Mapper) first carried by Landsat 4 (for a summary of Landsat satellites see <http://geo.arc.nasa.gov/sge/landsat/lpsum.html>). The Thematic Mapper provides a resolution as low as 30 m, a great improvement over the 70-m resolution of earlier sensors. The TM device collects reflected radiation in the visible, infrared (IR), and thermal (IR) region of the spectrum.

(3) In the late 1970’s, the regulation of Landsat was transferred from NASA to NOAA, and was briefly commercialized in the 1980s. The Landsat program is now oper-

ated by the USGS EROS Data Center (US Geological Survey Earth Resources Observation Systems; see <http://landsat7.usgs.gov/index.html>).

(4) As government sponsored programs have become increasingly commercialized and other countries develop their own remote sensors, NASA's focus has shifted from sensor development to data sharing. NASA's Data Acquisition Centers serves as a clearing-house for satellite data; these data can now be shared via the internet.

f. France's SPOT Satellite System. As a technology, remote sensing continues to advance globally with the introduction of satellite systems in other countries such as France, Japan, and India. France's SPOT (Satellite Pour l'Observation de la Terra) has provided reliable high-resolution (20 to 10 m resolution) image data since 1986.

(1) The SPOT 1, 2, and 3 offer both panchromatic data (P or PAN) and three bands of multispectral (XS) data. The panchromatic data span the visible spectrum without the blue (0.51-0.73 μm) and maintains a 10-m resolution. The multispectral data provide 20-m resolution, broken into three bands: Band 1 (Green) spans 0.50–0.59 μm , Band 2 (Red) spans 0.61–0.68 μm , and Band 3 (Near Infrared) spans 0.79–0.89 μm . SPOT 4 also supplies a 20-m resolution shortwave Infrared (mid IR) band (B4) covering 1.58 to 1.75 μm . SPOT 5, launched in spring 2002, provides color imagery, elevation models, and an impressive 2.5-m resolution. It houses scanners that collect panchromatic data at 5 m resolution and four band multispectral data at 10-m resolution (see Appendix D-“SPOT” file).

(2) SPOT 3 was decommissioned in 1996. SPOT 1, 2, 4, and 5 are operational at the time of this writing. For information on the SPOT satellites go to <http://www.spotimage.fr/home/system/introsat/seltec/welcome.htm>.

g. Future of Remote Sensing. The improved availability of satellite images coupled with the ease of image processing has lead to numerous and creative applications. Remote sensing has dramatically brought about changes in the methodology associated with studying earth processes on both regional and global scales. Advancements in sensor resolution, particularly spatial, spectral, and temporal resolution, broaden the possible applications of satellite data.

(1) Government agencies around the world are pushing to meet the demand for reliable and continuous satellite coverage. Continuous operation improves the temporal data needed to assess local and global change. Researchers are currently able to perform a 30-year temporal analysis using satellite images on critical areas around the globe. This time frame can be extended back with the incorporation of digital aerial photographs.

(2) Remote sensing has established itself as a powerful tool in the assessment and management of U.S. lands. The Army Corps of Engineers has already incorporated this technology into its nine business practice areas, demonstrating the tremendous value of remote sensing in civil works projects.

Chapter 3 Sensors and Systems

3-1 Introduction. Remotely sensed data are collected by a myriad of satellite and airborne systems. A general understanding of the sensors and the platforms they operate on will help in determining the most appropriate data set to choose for any project. This chapter reviews the nine business practice areas in USACE Civil Works and examines the leading questions to be addressed before the initiation of a remote sensing project. Airborne and satellite sensor systems are presented along with operational details such as flight path/orbits, swath widths, acquisition, and post processing options. Ground-based remote sensing GPR (Ground Penetrating Radar) is also introduced. This chapter concludes with a summary of remote sensing and GIS matches for each of the nine civil works business practice areas.

a. Industry Perspective on Image Acquisition. In the past 30 years, selection of remotely sensed imagery was confined by system constraints and only provided by a few vendors. Imagery that was available from archive, or that would become available due to orbital frequency, maintained numerous constraints; consequently ground coverage, rather than image resolution, was the primary concern. Additionally, minor consideration was given to the spectral characteristics of the target and the spectral bands available, as there were a limited number of imaging platforms. To an extent projects had to be tailored to fit the limitations of the data. This is no longer the case however, with significant technologic improvements and numerous product choices. Creative researchers are finding new applications in the on-going advancement of remote sensing.

b. Image Improvements. Satellite sensor system developers continue to improve image cost, resolution, spectral band choices, spectral data library sets, and value-added products or post-processing methods. Improvements in sensor development and affordability can be attributed to the commercialization and subsequent expansion of the remote sensing industry. NASA, other US governmental agencies, and foreign space agencies, such as those in Canada, France, India, and Japan, progressively enhance the industry by furthering current technologic advances in the remote sensing field. Consequently, the resolution constraints on data that existed 20 or more years ago are no longer an obstacle with the addition of these affordable higher resolution systems. Listed here are just a few examples of airborne and satellite data costs:

- AVHRR scene at 1 km GSD for < \$50
- Landsat TM scene at 30 m GSD for \$625
- Landsat ETM scene can be acquired for \$800
- ERS-1 SAR scene at 25 m GSD for \$2000
- ERS-2 SAR scene at 25 m GSD for \$1500.
- Vendors of high-resolution satellite imaging systems products (such as IKONOS or QUICKBIRD or other products with <4 m GSD [ground sampling distance is the spatial resolution measurement]) charge on a per area basis. The minimum area is 11 km² for approximately \$2000.

c. Archive Imagery. This can be accessed and purchased at a reduced rate. Some imaging systems can acquire new imagery at reasonable rates as well. It is now possible to tailor acquisitions to meet the specific needs of Corps projects. Costs presented in this manual will fluctuate, but generally become more affordable over time. The downward trend in cost applies to all aspects of remote sensing - data acquisition and the required software and hardware.

3-2 Corps 9—Civil Works Business Practice Areas. The spatial, spectral, and temporal requirements set by the goals in a Corps business practice area should be balanced with the economic limits of the project. To achieve this result, it is helpful to consider a few preliminary steps when planning an image data acquisition. Below is a review of the Corps 9 Civil Works Business Practice Areas. The steps that should be taken to determine the specific data requirements follow each business practice. A list of vendor services is presented along with details on the various platforms (airborne, satellite, and ground penetrating radar). The nine business practice areas in Civil Works of the Corps of Engineers and a listing of their operations follows:

a. Navigation.

- Responsible for navigation channels.
- Dredging for specified width and depth.
- Maintenance of 12,000 miles of inland waterways.
- Maintenance of 235 locks.
- 300 commercial harbors.
- 600 smaller harbors.

b. Flood Damage Reduction.

- Build and maintain levees.
- Maintenance of 383 dams and reservoirs.
- Advice on zoning, regulations and flood warning systems.
- Shore protection—protection from hurricane and coastal storms.
- Construction of jetties, seawalls, and beach sand renourishment.
- Responsibility for dam safety—inspection of Corps and other's dams

c. Environmental Missions.

- Ecosystem restoration—many small ecosystem restoration projects, and the larger Florida Everglades hydrologic restoration project.
- Environmental stewardship—protect forest and wildlife habitat; monitor water quality at reservoirs; operate several fish hatcheries; support national goal of “no net loss of wetlands”; and projects on conservation, preservation, restoration and wetland creation.
- Radioactive site cleanup—FUSRAP (Formerly Used Sites Remedial Action Program).

d. Wetlands and Waterways Regulation and Permitting.

- Support Clean Water Act.

- Authority over dumping, dredging and filling in Waters of the US (WoUS).
- Determine areas for protection as wetlands (under guidelines of 1987 Wetland Delineation Manual), and permitting for land use.
- Water supply—Washington DC aqueduct operation, manage water supply from Corps reservoirs and water use for agriculture in arid regions of South-western US
- Hydroelectric power—Corps operates 75 hydroelectric power plants.

e. Real Estate.

- Full range of services to Army and Air Force.
- Manage Contingency Real Estate Support Team (CREST).
- DOD agent for Recruiting Facilities Program, Homeowners Assistance Program and Defense National Relocation Program.

f. Recreation.

- Operate and maintain 2500 recreation areas at 463 lakes.
- Rangers are Dept. of Army employees.
- Corps is active in National Water Safety Program.

g. Emergency Response.

- Response to hurricanes, tornadoes, flooding, and natural disasters.
- Support to FEMA when activated by Federal Response Plan (FRP).
- Under FRP Corps has lead for public works and engineering missions.

h. Research and Development.

ERDC is composed of seven research laboratories for military, civil works and civilian infrastructure applications:

TEC—Topographic Engineering Center

CERL—Construction Engineering and Research Laboratory

CRREL—Cold Regions Research and Engineering Laboratory

WES-GSL—Waterways Experiment Station-Geotechnical and Structures Laboratory

WES-EL—Waterways Experiment Station-Environmental Laboratory

WES-CHL—Waterways Experiment Station-Coastal Hydraulics Laboratory

WES-ITL—Waterways Experiment Station-Information Technology Laboratory

i. Support to Others. This includes engineering and water resources support to state and Federal agencies, and to foreign countries.

3-3 Sensor Data Considerations (programmatic and technical).

a. Below is a list of preliminary steps and questions to consider when planning an image data acquisition. Answer these questions in light of the Corps Civil Works 9 Business Practice Areas before proceeding.

- What is the primary goal of the project?
Define the problem.
How can remote sensing be applied to assist in solving the problem?
- What spatial resolution is need?
Determine the minimum, maximum, and/ or optimal GSD (ground sampling distance).
- What is the target or what is being mapped?
High-resolution panchromatic (black and white) aerial photography may be sufficient.
Define what spectral bands are needed.
- Will field work be included in the project budget?
What detail is needed from the imagery?
- What spectral resolution is needed?
Set bandwidth and proximity.
- Determine timing and temporal resolution requirements.
Select season(s) and time frequencies.
- How urgent is the data needed?
To capture an emergency event or temporal phenomena an airborne system may need to be promptly employed.
- What repeat cycle do we need?
Each sensor system operates on a different cycle.
- When will ground truth data be collection?
Image data acquisition ideally coincides with ground truth data collection.
- What are the weather and light conditions?
Select radar or optical imagery or adjust acquisition timing to accommodate for variable atmospheric conditions.
- What level of processing will be performed by the vendor?
For example, choose basic processes such as radiometric, atmospheric, and geometric corrections should be considered.
- What accuracy do we want?
Set vertical and horizontal limits.
- Where is the project geographically located?
Specify upper left/ lower right hand corner Latitudes and Longitudes.

- What is the funding situation?
Chose a system and methods that will allow you to cost-effectively follow through on a project.
 - Do we need new or archived data?
Avoid wasting resources by soliciting imagery data that already exists. Contact TEC Image Office (TIO) to determine image data availability and purchasing procedures.
- b.* Here are some ancillary decisions to be made based on answers to the above questions.
- What field of view is needed?
Specify image overlap if one image is not sufficient. Be aware that aircraft and flight line paths control image overlap. Should either be altered then the overlap could be negatively affected (Figure 3-1).
 - What acquisition look direction?
Radar imagery taken in mountainous regions can have layover distortion and shadow regions; whereas nadir looking airborne imagery has less of that effect, so that equal amounts of backscatter and transmission are collected on both sides of the feature.
 - Are commercial analytical services needed?
Will post-processing of the imagery be accomplished in-house, or does this require external expertise — an example is the processing of radar IFSAR into elevation data, which is a very special technique done by dedicated software on dedicated hardware and not generally done in-house. Below are examples of vendor post-processing services.

Figure 3-1. In this CAMIS image a decrease in aircraft altitude (due to circumstances beyond the operators control) reduced the pixel size and subsequently decreased the image scene. After mosaicing the individual scenes the side overlaps created “holidays” or gaps in the data. Taken from Campbell (2003).

3-4 Value Added Products. Examples of post-processing done on imagery are listed here with URLs to some of the companies that do the work (sometimes called level 2 or value added products).

- Earthsat Corporation <http://www.earthsat.com/ip/prodsvc/> offers geocoding, orthorectification, seamless mosaics, data fusion, and spectral transforms including simulated true color, minimum noise fraction (MNF), vegetation suppression, and decorrelation stretch. They offer hyperspectral processing such as atmospheric correction, automatic endmember selection, pixel unmixing, vegetation stress mapping, and aircraft motion compensation.
- The SPOT Corporation <http://www.spot.com/home/proser/welcome.htm> offers SPOTView (image map product), land use/land cover (thematic product), elevation/terrain mapping (3-D products), and vegetation products.
- Vectorization Services <http://www.vectorizationservices.com/services.htm> offers rectification and orthorectification, enhancement, mosaicing, fusion and image interpretation.
- Agricast <http://www.agricast.com/> offers value-added products for precision farming, agriculture, and range management.
- Science Applications International Corporation (SAIC) <http://www.saic.com/imagery/remote.html> offers many value added products for industries from agriculture to utilities. See their web site for the complete list.
- Emerge <http://www.emergeweb.com/Public/info/productsPage.asp> offers digital ortho products and mosaics from airborne imagery.
- The J.W. Sewall Company http://www.jws.com/pages/core_sevices.html offers photogrammetric mapping, cadastral mapping, municipal GIS development, energy and telecommunications services, and natural resources consulting.
- Analytical Imaging and Geophysics <http://www.aigllc.com/research/intro.htm> offers analysis of multispectral, hyperspectral and SAR imagery with map production and field verification.
- Spectral International, Inc. <http://www.pimausa.com/services.html> offers analytical services, consulting and hyperspectral image processing.
- Earthdata <http://www.earthdata.com/index2.htm> offers digital orthophotos, topographic maps, planimetric maps, and LIDAR 3-D elevation data.
- Intermap Technologies <http://www.intermaptechnologies.com/products.htm> offers IFSAR DEMs, DSMs, DTMs, and orthorectified radar images.
- 3Di <http://www.3dicorp.com/rem-products.html> offers LIDAR DEMs, orthorectified imagery, contour mapping, wetlands mapping, vegetation mapping, 3D perspective image drapes, and volumetric analysis.
- Terrapoint <http://www.terrapoint.com/Products2.htm> offers LIDAR elevation data sets, DTMs, DEMs, canopy DTMs, building heights, land records, and floodmaps.
- i-cubed <http://www.i3.com> offers information integration and imaging
- Leica Geosystems <http://www.gis.leica-geosystems.com> offers GIS and mapping.
- PhotoScience, Inc. <http://www.photoscience.com> offers aerial photography, photogrammetry, GPS survey, GIS services, image processing

3-5 Aerial Photography. Aerial photography is a highly useful mapping tool and maintains the highest spatial resolution of any of the remote sensing systems. Standard 9-in. (22.9 cm) aerial photos used for mapping and site identification are collected and made available through commercial companies. USGS generates digital elevation model (DEM) data and stereo classification of ground cover from aerial photography. These data are derived from the National Aerial Photography Program (NAPP), formally the National High Altitude Program (NHAP). The NAPP products are quarter quad-centered photographs of the entire contiguous US, acquired every 5 years over 2-year intervals since 1990. NAPP photography is acquired at 20,000 ft (~600 m) above mean terrain with a 6-in. (~15 cm) focal length lens. The flight lines are quarter quad-centered on the 1:24,000-scale USGS maps. NAPP photographs have an approximate scale of 1:40,000, and collect black-and-white or color infrared, as specified by state or Federal requirements. The St. Louis District of the Corps has several airborne contracts in place as well.

a. Softcopy photogrammetry is the semi-automatic processing of aerial photos after they have been digitally scanned into files and transferred into a computer. Once in digital form, the processes of stereo imaging, stereo compilation, aerial triangulation, topographic mapping, ortho-rectification, generation of DEMs, DTMs, and DSMs and digital map generation can be carried out.

b. Aerial photos are geometrically corrected using the fiducial marks and a camera model and projected into the ground coordinates. Images within a stereo overlap are adjusted using a triangulation algorithm so that they fit within the constraints of the ground control point information. At the end of the triangulation, individual stereo models are mathematically defined between stereo images. Topographic information is extracted from the images using autocorrelation techniques that match image patterns within a defined radius. By using parallax created by the different angle shots, elevation is measured from the distance of matching pixels. A terrain model is used to create an ortho-rectified image from the original photo that is precision geocoded and an ancillary Digital Surface Model (DSM) is available.

c. Some of the companies that contract with USACE for aerial photography include:

- Highland Geographic Inc. <http://www.highlandgeographic.com>
- James W. Sewall Company <http://www.sewall.com>
- Alcor Technologies Limited <http://www.alcortechnologies.com>
- Aero-Metric Inc. <http://www.aerometric.com>
- PhotoScience, Inc. <http://www.photoscience.com>

3-6 Airborne Digital Sensors. The advancement of airborne systems to include high resolution digital sensors is becoming available through commercial companies. These systems are established with onboard GPS for geographic coordinates of acquisitions, and real time image processing. Additionally, by the time the plane lands on the ground, the data can be copied to CDROM and be available for delivery to the customer with a basic level of processing. The data at this level would require image calibration and additional

processing. The data at this level would require image calibration and additional processing. See Appendix F for a list of airborne system sensors.

3-7 Airborne Geometries. There are several ways in which airborne image geometry can be controlled. Transects should always be flown parallel to the principle plane to the sun, such that the BRDF (bi-directional reflectance distribution function) is symmetrical on either side of the nadir direction. The pilot should attempt to keep the plane level and fly straight line transects. But since there are always some attitude disturbances, GPS and IMU (inertial measuring unit) data can be used in post-processing the image data to take out this motion. The only way of guaranteeing nadir look imagery is to have the sensor mounted on a gyro-stabilized platform. Without this, some angular distortion of the imagery will result even if it is post-processed with the plane's attitude data and an elevation model (i.e., sides of buildings and trees will be seen and the areas hidden by these targets will not be imaged). Shadow on one side of the buildings or trees cannot be eliminated and the dynamic range of the imagery may not be great enough to pull anything out of the shadow region. The only way to minimize this effect is to acquire the data at or near solar noon.

3-8 Planning Airborne Acquisitions.

a. Planning airborne acquisitions requires both business and technical skills. For example, to contract with an airborne image acquisition company, a sole source claim must be made that this is the only company that has these special services. If not registered as a prospective independent contractor for a Federal governmental agency, the company may need to file a Central Contractor Registration (CCR) Application, phone (888-227-2423) and request a DUNS number from Dun & Bradstreet, phone (800-333-0505). After this, it is necessary for the contractee to advertise for services in the Federal Business Opportunities Daily (FBO Daily) <http://www.fbodaily.com>. Another way of securing an airborne contractor is by riding an existing Corps contract; the St. Louis District has several in place. A third way is by paying another governmental agency, which has a contract in place. If the contractee is going to act as the lead for a group acquisition among several other agencies, it may be necessary to execute some Cooperative Research and Development Agreements (CRDAs) between the contractee and the other agencies. As a word of caution, carefully spell out in the legal document what happens if the contractor, for any reason, defaults on any of the image data collection areas. A data license should be spelled out in the contract between the parties.

b. Technically, maps must be provided to the contractor of the image acquisition area. They must be in the projection and datum required, for example Geographic and WGS84 (*World Geodetic System* is an earth fixed global reference frame developed in 1984). The collection flight lines should be drawn on the maps, with starting and ending coordinates for each straight-line segment. If an area is to be imaged then the overlap between flight lines must be specified, usually 20%. If the collection technique is that of overlapping frames then both the sidelap and endlap must be specified, between 20 and 30%. It is a good idea to generate these maps as vector coverages because they are easily changed when in that format and can be inserted into formal reports with any caption desired later.

The maximum angle allowable from nadir should be specified. Other technical considerations that will affect the quality of the resulting imagery include: What sun angle is allowable? What lens focal length is allowable? What altitude will the collection be flown? Will the imagery be flown at several resolutions or just one? Who will do the orthorectification and mosaicing of the imagery? Will DEMs, DTMs, or DSMs be used in the orthorectification process? How will unseen and shadow areas be treated in the final product? When planning airborne acquisitions, these questions should be part of the decision process.

3-9 Bathymetric and Hydrographic Sensors.

a. The Scanning Hydrographic Operational Airborne Lidar Survey (SHOALS <http://shoals.sam.usace.army.mil/default.htm>) system is used in airborne lidar bathymetric mapping. The Joint Airborne Lidar Bathymetry Technical Center of Expertise (JALBTCX) is a partnership between the South Atlantic Division, US Army Corps of Engineers (USACE), the Naval Meteorology and Oceanography Command and Naval Oceanographic Office and USACE's Engineer Research and Development Center. JALBTCX owns and operates the SHOALS system. SHOALS flies on small fixed wing aircraft, Twin Otter, or on a Bell 212 helicopter. The SHOALS system can collect data on a 4-m grid with vertical accuracy of 15 cm. In clear water bathymetry can be collected at 2–3 times Secchi depth or 60 m. It does not work in murky or sediment-laden waters.

b. The Corps uses vessels equipped with acoustic transducers for hydrographic surveys. The USACE uses multibeam sonar technology in channel and harbor surveys. Multibeam sonar systems are used for planning the depth of dredging needed in these shallow waters, where the accuracy requirement is critical and the need for correct and thorough calibration is necessary. USACE districts have acquired two types of multibeam transducers from different manufacturers, the Reson Seabat and the Odom Echoscan multibeam. The navigation and acquisition software commonly in use by USACE districts is HYPACK and HYSWEEP, by Coastal Oceanographics Inc. For further information see the web site at https://velvet.tec.army.mil/access/milgov/fact_sheet/multibea.html (due to security restrictions this site can only be accessed by USACE employees).

3-10 Laser Induced Fluorescence.

a. Laser fluorosensors detect a primary characteristic of oil, namely their characteristic fluorescence spectral signature and intensity. There are very few substances in the natural environment that fluoresce, those that do, fluoresce with sufficiently different spectral signatures and intensities that they can be readily identified. The Laser Environmental Airborne Fluorosensor (LEAF) is the only sensor that can positively detect oil in complex environments including, beaches and shorelines, kelp beds, and in ice and snow. In situations where oil contaminates these environments, a laser fluorosensor proves to be invaluable as a result of its ability to positively detect oil http://www.etcentre.org/home/water_e.html.

b. Other uses of laser fluorosensors are to detect uranium oxide present in facilities, abandoned mines, and spill areas that require remediation. See Special Technologies Laboratory of Bechtel, NV, <http://www.nv.doe.gov/business/capabilities/lifi/>.

3-11 Airborne Gamma.

a. An AC-500S Aero Commander aircraft is used by the National Operational Hydrologic Remote Sensing Center (NOHRSC) to conduct aerial snow survey operations in the snow-affected regions of the United States and Canada. During the snow season (January–April), snow water equivalent measurements are gathered over a number of the 1600+ pre-surveyed flight lines using a gamma radiation detection system mounted in the cabin of the aircraft. During survey flights, this system is flown at 500 ft (152 m) above the ground at ground speeds ranging between 100 and 120 knots (~51 to 62 m/s). Gamma radiation emitted from trace elements of potassium, uranium, and thorium radioisotopes in the upper 20 cm of soil is attenuated by soil moisture and water mass in the snow cover. Through careful analysis, differences between airborne radiation measurements made over bare ground are compared to those of snow-covered ground. The radiation differences are corrected for air mass attenuation and extraneous gamma contamination from cosmic sources. Air mass is corrected using output from precision temperature, radar altimeter, and pressure sensors mounted on and within the aircraft. Output from the snow survey system results in a mean areal snow water equivalent value within ± 1 cm. Information collected during snow survey missions, along with other environmental data, is used by the National Weather Service (NWS), and other agencies, to forecast river levels and potential flooding events attributable to snowmelt water runoff (<http://www.aoc.noaa.gov/>).

b. Other companies use airborne gamma to detect the presence of above normal gamma ray count, indicative of uranium, potassium, and thorium elements in the Earth's crust (for example, Edcon, Inc., <http://www.edcon.com>, and the Remote Sensing Laboratory at Bechtel, Nevada). The USGS conducted an extensive survey over the state of Alaska as part of the National Uranium Resource Evaluation (NURE) program that ran from 1974 to 1983, <http://edc.usgs.gov/>.

3-12 Satellite Platforms and Sensors.

a. There are currently over two-dozen satellite platforms orbiting the earth collecting data. Satellites orbit in either a circular geo-synchronous or polar sun-synchronous path. Each satellite carries one or more electromagnetic sensor(s), for example, Landsat 7 satellite carries one sensor, the ETM+, while the satellite ENVISAT carries ten sensors and two microwave antennas. Some sensors are named after the satellite that carries them, for instance IKONOS the satellite houses IKONOS the sensor. See Appendices D and E for a list of satellite platforms, systems, and sensors.

b. Sensors are designed to capture particular spectral data. Nearly 100 sensors have been designed and employed for long-term and short-term use. Appendix D summarizes details on sensor functionality. New sensors are periodically added to the family of ex-

isting sensors while older or poorly designed sensors become decommissioned or de-funct. Some sensors are flown on only one platform; a few, such as MODIS and MSS, are on-board more than one satellite. The spectral data collected may span the visible (optical), blue, green, microwave, MIR/SWIR, NIR, Red, or thermal IR. Sensors can detect single wavelengths or frequencies and/or ranges of the EM spectrum.

3-13 Satellite Orbits.

a. Remote sensing satellites are placed into different orbits for special purposes. The weather satellites are geo-stationary, so that they can image the same spot on the Earth continuously. They have equatorial orbits where the orbital period is the same as that of the Earth and the path is around the Earth's equator. This is similar to the communication satellites that continuously service the same area on the Earth (Figure 3-2).

Figure 3-2. Satellite in Geostationary Orbit. Courtesy of the Natural Resources Canada.

b. The remaining remote sensing satellites have near polar orbits and are launched into a sun synchronous orbit (Figure 3-3). They are typically inclined 8 degrees from the poles due to the gravitational pull from the Earth's bulge at the equator; this allows them to remain in orbit. Depending on the swath width of the satellite (if it is non-pointable), the same area on the Earth will be imaged at regular intervals (16 days for Landsat, 24 days for Radarsat).

Figure 3-3. Satellite Near Polar Orbit, Courtesy of the Natural Resources Canada.

3-14 Planning Satellite Acquisitions. Corps satellite acquisition must be arranged through the Topographic Engineering Center (TEC) Imagery Office (TIO). It is very easy to transfer the cost of the imagery to TEC via the Corps Financial Management System (CFMS). They will place the order, receive and duplicate the imagery for entry into the National Imagery and Mapping Agency (NIMA) archive called the Commercial Satellite Imagery Library (CSIL), and send the original to the Corps requester. They buy the imagery under a governmental user license contract that licenses free distribution to other government agencies and their contractors, but not outside of these. It is important for Corps personnel to adhere to the conditions of the license. Additional information concerning image acquisition is discussed in Chapter 4 (Section 4-1).

a. Turn Around Time. This is another item to consider. That is the time after acquisition of the image that lapses before it is shipped to TEC-TIO and the original purchaser. Different commercial providers handle this in different ways, but the usual is to charge an extra fee for a 1-week turn around, and another fee for a 1 to 2 day turn around. For example, SPOT Code Red programmed acquisition costs an extra \$1000 and guarantees shipment as soon as acquired. The ERS priority acquisition costs an extra \$800 and guarantees shipment within 7 days, emergency acquisition cost \$1200 and guarantees shipment within 2 days, and near real time costs an extra \$1500 and guarantees shipment as soon as acquired. Also arrangement may be made for ftp image transfers in emergency situations. Costs increase in a similar way with RADARSAT, IKONOS, and QuickBird satellite imaging systems.

b. Swath Planners.

- Landsat acquired daily over the CONUS, use DESCW swath planner on PC running at least Windows 2000 for orbit locations. <http://earth.esa.int/services/descw/>
- ERS, JERS, ENVISAT—not routinely taken, use DESCW swath planner on PC running at least Windows 2000 for orbit locations. <http://earth.esa.int/services/descw/>
- RADARSAT—not routinely acquired, contact the TEC Imagery Office regarding acquisitions of Radarsat data.
- Other commercial imaging systems, contact the TEC Imagery Office regarding acquisitions.

3-15 Ground Penetrating Radar Sensors. Ground penetrating radar (GPR) uses electromagnetic wave propagation and back scattering to image, locate, and quantitatively identify changes in electrical and magnetic properties in the ground. Practical platforms for the GPR include on-the-ground point measurements, profiling sleds, and near-ground helicopter surveys. It has the highest resolution in subsurface imaging of any geophysical method, approaching centimeters. Depth of investigation varies from meters to several kilometers, depending upon material properties. Detection of a subsurface feature depends upon contrast in the dielectric electrical and magnetic properties. Interpretation of ground penetrating radar data can lead to information about depth, orientation, size, and shape of buried objects, and soil water content.

a. GPR is a fully operational Cold Regions Research and Engineering Laboratory (CRREL) resource. It has been used in a variety of projects: e.g., in Antarctica profiling for crevasses, in Alaska probing for subpermafrost water table and contaminant pathways, at Fort Richardson probing for buried chemical and fuel drums, and for the ice bathymetry of rivers and lakes from a helicopter.

b. CRREL has researched the use of radar for surveys of permafrost, glaciers, and river, lake and sea ice covers since 1974. Helicopter surveys have been used to measure ice thickness in New Hampshire and Alaska since 1986. For reports on the use of GPR within cold region environments, a literature search from the CRREL website (<http://www.crrel.usace.army.mil/>) will provide additional information. Current applications of GPR can be found at <http://www.crrel.usace.army.mil/sid/gpr/gpr.html>.

c. A radar pulse is modulated at frequencies from 100 to 1000 MHz, with the lower frequency penetrating deeper than the high frequency, but the high frequency having better resolution than the low frequency. Basic pulse repetition rates are up to 128 Hz on a radar line profiling system on a sled or airborne platform. Radar energy is reflected from both surface and subsurface objects, allowing depth and thickness measurements to be made from two-way travel time differences. An airborne speed of 25 m/s at a low altitude of no more than 3 m allows collection of line profile data at 75 Hz in up to 4 m of depth with a 5-cm resolution on 1-ft (30.5 cm)-grid centers. Playback rates of 1.2 km/min. are possible for post processing of the data.

d. There are several commercial companies that do GPR surveys, such as Blackhawk Geometrics and Geosphere Inc., found on the web at <http://www.blackhawkgeo.com>, and <http://www.geosphereinc.com>.

3-16 Match to the Corps 9—Civil Works Business Practice Areas. Match to the Corps business practice areas presupposes that everything about remote sensing for a particular ground or water parameter is known or works. However, this is not the case. Mapping for the amount of visible detail for a particular business area can be and has been readily listed in the National Imagery Interpretability Rating Scale (NIIRS). An approximate match between NIIRS level and GSD is given in the following.

a. *Navigation Needs*—lock and dam modification and construction, harbor facilities construction, channel dredging.

(1) How can remote sensing help in the maintenance, dredging, and planning for new construction?

(2) Remote sensing match:

- Hydrographic surveys creating maps of underwater depth and obstructions.
- Maps of original land and water area to be converted.
- Elevation profiles of the areas.
- Maps of the surrounding area to meet requirement of no net loss of wetlands.
- See Paragraph 3-3.

b. *Flood Damage Reduction Needs*—levee, dam, jetty, and seawall construction and beach sand re-nourishment projects, installation of flood warning systems.

(1) How can remote sensing help in planning for construction, for beach sand re-nourishment projects, and for the installation of flood warning systems?

(2) Remote sensing match:

- Maps of construction and surrounding areas.
- Elevation profiles of the areas.
- Beach maps and elevation profiles and near shore bathymetry.
- Levee top elevations for flood warning systems.
- See Paragraph 3-3.

c. *Environmental Mission Needs*—ecosystem restorations, protection of forest and wildlife habitat, water quality monitoring, wetland creation, radioactive and abandoned mine lands (AML) cleanup.

(1) How can remote sensing help in planning for ecosystem restorations, monitoring forest and wildlife habitat and water quality, and for wetland creation and AML cleanup?

(2) Remote sensing match:

- Maps of current ecosystem, wetlands, rivers, streams, aquifers, natural vegetation.
- Maps of forest types and vegetation communities.
- Map chlorophyll and sediments in lakes and reservoirs.
- Map mine sites, polluted drainage and stream and watershed areas.
- See “Sensor Data Considerations (programmatic and technical).”

d. Wetlands and Waterways Needs—authority over dumping, dredging, and filling in Waters of the US, delineate wetlands, monitor water quality of water supplies, planning conservation of water in the arid southwest.

(1) How can remote sensing help in delineating wetlands and issuing permits for dumping, dredging, and filling, monitoring water quality of water supplies, and in management of water in arid and agricultural regions of the west and southwest?

(2) Remote sensing match:

- Maps delineating wetlands.
- Maps of water quality and sedimentation of water supplies.
- Maps of snow/ water equivalency and reservoir capacity and agriculture demand.
- See Paragraph 3-3.

e. Real Estate Needs—locations and types.

(1) How can remote sensing help in planning real estate location and type?

(2) Remote sensing match:

- Mapping urban, suburban and city locations for entry into a GIS.
- see “Sensor Data Considerations (programmatic and technical).”

f. Recreation—maintain 2500 recreation areas.

(1) How can remote sensing help in maintenance and operation of recreation areas?

(2) Remote sensing match:

- Mapping and classification of forests and habitat in parks and monitoring water quality of lakes and reservoirs.
- See Paragraph 3-3.

g. Emergency Response—response to hurricanes and natural disasters.

(1) How can remote sensing help in response to natural disasters?

(2) Remote sensing match:

- Immediate mapping of disaster area.
- High resolution mapping to determine extent of personal damage (houses) and temporary roofing capability (FEMA regulated at 50 % roof rafters still in place).
- See Paragraph 3-3.

h. Research and Development—Seven research laboratories and support to the Nation's civil works sector.

(1) How can remote sensing help in the work carried out by the seven research laboratories and support the nation's civil works sector?

(2) Remote sensing match:

- Mapping and classification in mission areas and specific projects.
- Development of new methods and techniques of remote sensing and processing.
- See Paragraph 3-3.

i. Support to Others—other state and Federal agencies, foreign countries, and reimbursable work done.

(1) How can remote sensing help in work done for other state and federal agencies, foreign countries and in reimbursable work done?

(2) Remote sensing match:

- Mapping, remote sensing and GIS training, and classification in ongoing projects
- See Paragraph 3-3.

Chapter 4 Data Acquisition and Archives

4-1 Introduction.

a. *USACE Image Acquisition Standard Operating Procedure.* Image data should be acquired following the established protocol developed by ERDC's TEC Imaging Office (TIO)*. The protocol allows for efficient monitoring of image acquisition and archival practice. There are numerous advantages in using TIO's image procedure. The most significant advantage in using TIO's protocol is cost savings. This savings is the result of on-going contracts between satellite data vendors and the federal government. In addition to a reduced cost, TIO is able to broaden the image-share licensing allowing USACE full access to previously purchased data. The image-share licensing agreement is funded by NIMA who in turn allows all DoD and Title 50 Intelligence members full use of imagery data. In other words, once a USACE researcher has acquired imagery all other USACE districts can legally access these data at no charge. These data are also available to contractors working under a USACE contract.

b. *SOP.* The standard operating procedure (SOP) for acquiring new data is defined by the EM 1110-1-2909 (Appendix I), which states that no imagery shall be purchased from a commercial vendor without first coordinating with TIO (Appendix G). TIO has streamlined image data purchases and provides quick and efficient turn-around. The only exception to this SOP is in the case of acquiring free imagery downloaded from the Internet. A handful of governmental and commercial agencies (such as NASA and SpaceImaging) have made select satellite images available at no cost. These sites may require a login and can provide software for viewing data free of charge.

Ordering Commercial Satellite Imagery

"No imagery shall be purchased from a commercial vendor without first coordinating with the TIO. Any U.S. Army organization with commercial satellite imagery requirements must forward their commercial satellite imagery requirements to TEC for research, acquisition, and distribution of the data."

Contact TEC's Imagery Office, using one of the following methods:

Web Site: WWW.tec.army.mil/tio/index.htm

Email: TIO@tec.army.mil

ERDC (Engineer Research and Development Center) includes the seven Corps of Engineers research laboratories.

TEC (Topographic Engineering Center) serves the Corps of Engineers and the Department of Defense. TIO (TEC Imaging Office) monitors and coordinates all USACE image requirements with commercial vendors and public data libraries.

c. Placing Image Orders. Commercial imagery and aerial photo requests can be placed via email, memorandum, fax, or phone. The following image requirements should be determined prior to contacting TIO.

1. Geographic area of interest in latitude/longitude coordinates in degrees and minutes (or path/row if known).
2. Acceptable date range for data coverage; cloud cover and quality restrictions.
3. Satellite system/sensor.
4. Desired end product (digital or hard copy and preferred media).
5. Mailing and electronic address and phone number.

Consider the timing requirements for the project. For projects not involving emergencies or hazards satellite data may be delivered by regular mail. TIO can also deliver data by FEDEX and FTP. The TIO performs an image data search through the CSIL (Commercial Satellite Image Library). When data is available in the CSIL, the TIO receives a CD of the data, and copies the data for the customer.

DO

Verify your geo-coordinates.

Review imagery for accuracy and quality make sure the imagery covers your area of interest.

You may call a commercial satellite vendor to discuss technical problems encountered after you receive the imagery from the TEC Imagery Office (i.e.: accuracy and quality problems).

DO NOT

Contact the vendors on your own without first communicating with the TIO.

During the acquisition stage, do not consult the vendor's technical staff to have additional work done that is not stated in the written proposal.

d. Points of Contact (as of September 2003).

- Army Commercial Imagery Acquisition Program Manager—Mary Pat Santoro, 703-428-6903
- TIO Team Leader—Mary Brenke, 703-428-6909
- TIO Team Member—Alana Hubbard, 703-428-6717

4-2 Specifications for Image Acquisition. The TEC Imagery Office (TIO) is the first stop for obtaining imagery for the USACE, contact Mary Brenke (703-428-6909) or Alana Hubbard (703-428-6717). But, before contacting them, some basic information about what is wanted should be put together. A list follows:

- Geographic coordinates—upper left and lower right corner latitude–longitude coordinates or, if known, the path/row of a Landsat scene, the K/J of a SPOT scene; the orbit and frame number for a SAR image from ERS, Radarsat, JERS, or Envisat.
- Acceptable coverage dates.
- Acceptable percentage of cloud cover, image quality, and off nadir angle limit.
- Satellite sensor or sensors.
- Image format—digital tape, CDROM, projection wanted, projection parameters, tar (*tape archive retrieval* is a compression file format), satellite format, compression or uncompressed.
- Your name, phone, FAX, e-mail, mailing address.
- Payment—TIO will determine the correct cost for the imagery, which will be purchased for you by the USGS Eros Data Center (EDC). You will have to do a Military Interdepartmental Purchase Request (MIPR) of the money to EDC, EDC will send the imagery to the TIO for duplication and archiving in CSIL at NIMA, the original image will be forwarded to you.

4-3 Satellite Image Licensing. The license for satellite imagery is extended to a no cost duplication of the data for any DOD agencies and their contractors when the imagery is bought through the TEC-TIO contract with NIMA and the USGS EROS Data Center. Beyond that, the license specifically states that no other duplication of the unprocessed data is allowed.

4-4 Image Archive Search and Cost. The following is a compilation of archive search sources, along with web site addresses and the approximate cost of imagery. Data costs reflect new purchases and archive data rates at the time of the release of this manual.

<i>a. USGS EROS Data Center.</i>		http://earthexplorer.usgs.gov
LANDSAT (MSS, TM4 & 5)		\$ 425 - 2700.00
LANDSAT7 (ETM)		\$ 600
DOQQ		First Image \$ 45.00 Additional images: \$ 7.50 – Pan \$ 15.00 - Color
Full Orbit AVHRR		\$ 50
DEMs and DLGs		no cost
ALI (Landsat mimic 37km by 42km)	\$ 500 – 2800	http://eo1.usgs.gov/
Hyperion (hyperspectral 7.7km by 42km)	\$ 500 - 2800

4-5 Specifications for Airborne Acquisition. Maps must be provided to the contractor of the image acquisition area. They must be in the projection and datum required, for example Geographic and WGS84. The collection flight lines should be drawn on the maps with starting and ending coordinates for each straight-line segment. If an area is to be imaged, then the overlap between flight lines must be specified, usually 20%. If the collection technique is that of overlapping frames, then both the sidelap and endlap must be specified, between 20 and 30%.

4-6 Airborne Image Licensing. Licenses for data collected by aircraft vary. The contractor must read and agree to the terms. Some state that there are no conditions, some state that the data can be passed or resold to others after a certain period of time, some state the contractor is the sole owner of the data and that they can never be passed without their written permission.

4-7 St. Louis District Air-Photo Contracting. The St. Louis District has an extensive Geodesy, Cartography, and Photogrammetry (GC&P) Section. Photogrammetrists as certified by the American Society of Photogrammetry and Remote Sensing (ASPRS) have many years of experience in aerial photography, surveying, mapping and in the A-E Contracting of these services. The GC&P section is currently responsible for the technical management of all aerial photography and mapping projects within the St. Louis District. They provide contracting services for all photogrammetric mapping projects for other government agencies, as well as other Corps of Engineers Districts.

a. Their experts in photogrammetry can provide assistance in developing contracts, scopes of work, government estimates or negotiation assistance. Technical guidance is provided in the development, acquisition, accuracy, and utilization of base topographic and planimetric mapping. They also provide advice on remote sensing data, environmental data sets, and engineering data to be incorporated into Geographic Information Systems (GIS) to assist engineers and scientists in Corps of Engineers project work.

b. The Point of Contact at the St. Louis District is Dennis Morgan (314)-331-8373. Appendices H and I include example contracts of a Statement of Work (SOW) and a Memorandum of Understanding (MOU).

Chapter 5

Processing Digital Imagery

5-1 Introduction. Image processing in the context of remote sensing refers to the management of digital images, usually satellite or digital aerial photographs. Image processing includes the display, analysis, and manipulation of digital image computer files. The derived product is typically an enhanced image or a map with accompanying statistics and metadata. An image analyst relies on knowledge in the physical and natural sciences for aerial view interpretation combined with the knowledge of the nature of the digital data (see Chapter 2). This chapter will explore the basic methods employed in image processing. Many of these processes rely on concepts included in the fields of geography, physical sciences, and analytical statistics.

5-2 Image Processing Software.

a. Imaging software facilitates the processing of digital images and allows for the manipulation of vast amounts of data in the file. There are numerous software programs available for image processing and image correction (atmospheric and geometric corrections). A few programs are available as share-ware and can be downloaded from the internet. Other programs are available through commercial vendors who may provide a free trial of the software. Some vendors also provide a tutorial package for testing the software.

b. The various programs available have many similar processing functions. There may be minor differences in the program interface, terminology, metadata files (see below), and types of files it can read (indicated by the file extension). There can be a broad range in cost. Be aware of the hardware requirements and limitations needed for running such programs. An on-line search for remote sensing software is recommended to acquire pertinent information concerning the individual programs.

5-3 Metadata.

a. Metadata is simply ancillary information about the characteristics of the data; in other words, it is data about the data. It describes important elements concerning the acquisition of the data as well as any post-processing that may have been performed on the data. Metadata is typically a digital file that accompanies the image file or it can be a hardcopy of information about the image. Metadata files document the source (i.e., Landsat, SPOT, etc.), date and time, projection, precision, accuracy, and resolution. It is the responsibility of the vendor and the user to document any changes that have been applied to the data. Without this information the data could be rendered useless.

b. Depending on the information needed for a project, the metadata can be an invaluable source of information about the scene. For example, if a project centers on change detection, it will be critical to know the dates in which the image data were collected. Numerous agencies have worked toward standardizing the documentation of metadata in an effort to simplify the process for both vendors and users. The Army Corps of Engineers follows the Federal Geographic Data Committee (FGDC) standards for metadata

(go to <http://geology.usgs.gov/tools/metadata/standard/metadata.html>). The importance of metadata cannot be overemphasized.

5-4 Viewing the Image. Image files are typically displayed as either a gray scale or a color composite (see Chapter 2). When loading a gray scale image, the user must choose one band for display. Color composites allow three bands of wavelengths to be displayed at one time. Depending on the software, users may be able to set a default band/color composite or designate the band/color combination during image loading.

5-5 Band/Color Composite. A useful initial composite (as seen in Figure 5-1a) for a Landsat TM image is Bands 3, 2, 1 (RGB). This will place band 3 in the red plane, band 2 in the green plane, and band 1 in the blue plane. The resultant image is termed a true-color composite and it will resemble the colors one would observe in a color photograph. Another useful composite is Bands 4, 3, 2 (R, G, B), known as a false-color composite (Figure 5-1b). Similar to a false-color infrared photograph, this composite displays features with color and contrast that differ from those observed in nature. For instance, healthy vegetation will be highlighted by band 4 and will therefore appear red. Water and roads may appear nearly black.

a. True-color Landsat TM composite 3, 2, 1 (RGB respectively).

b. False color composite 4, 3, 2.

Figure 5-1. Figure 5-1a is scene in which water, sediment, and land surfaces appear bright. Figure 5-1b is a composite that highlights healthy vegetation (shown in red); water with little sediment appears black. Images developed for USACE Prospect #196 (2002).

5-6 Information About the Image. Once the image is displayed it is a good idea to become familiar with the characteristics of the data file. This information may be found in a separate metadata file or as a header file embedded with the image file. Be sure to note the pixel size, the sensor type, data, the projection, and the datum.

5-7 Datum.

a. A geographic datum is a spherical or ellipsoidal model used to reference a coordinate system. Datums approximate the shape and topography of the Earth. Numerous

datums have evolved, each developed by the measurement of different aspects of the Earth's surface. Models are occasionally updated with the use of new technologies. For example, in 1984 satellites carrying GPS (global position systems) refined the World Geodetic System 1927 (WGS-27); the updated datum is referred to as WGS-84 (World Geodetic System-1984). Satellite data collected prior to 1984 may have coordinates linked to the WGS-27 datum. Georeferencing coordinates to the wrong datum may result in large positional errors. When working with multiple images, it is therefore important to match the datum for each image.

b. Image processing software provide different datums and will allow users to convert from one datum to another. To learn more about geodetic datums go to http://www.ngs.noaa.gov/PUBS_LIB/Geodesy4Layman/geo4lay.pdf.

5-8 Image Projections.

a. Many projects require precise location information from an image as well as geocoding. To achieve these, the data must be georeferenced, or projected into a standard coordinate system such as Universal Transverse Mercator (UTM), Albers Conical Equal Area, or a State Plane system. There are a number of possible projections to choose from, and a majority of the projections are available through image processing software. Most software can project data from one map projection to another, as well as unprojected data. The latter is known as rectification. Rectification is the process of fitting the grid of pixels displayed in an image to the map coordinate system grid (see Paragraph 5-14).

b. The familiar latitude and longitude (Lat/Long) is a coordinate system that is applied to the globe (Figure 5-2). These lines are measured in degrees, minutes, and seconds (designated by °, ', and " respectively). The value of one degree is given as 60 minutes; one minute is equivalent to 60 seconds ($1^{\circ} = 60'$; $1' = 60''$). It is customary to present the latitude value before the longitude value.

5-9 Latitude. Latitude lines, also known as the parallels or parallel lines, are perpendicular to the longitude lines and encircle the girth of the globe. They are parallel to one another, and therefore never intersect. The largest circular cross-section of the globe is at the equator. For this reason the origin of latitude is at the equator. Latitude values increase north and south away from the equator. The north or south direction must be reported when sighting a coordinate, i.e., 45°N. Latitude values range from 0 to 90°, therefore the maximum value for latitude is 90°. The geographic North Pole is at 90°N while the geographic South Pole is at 90°S

Figure 5-2. Geographic projection.

5-10 Longitude. The lines of longitude pass through the poles, originating at Greenwich, England (0° longitude) and terminating in the Pacific (180°). Because the Earth's spheroidal shape approximates a circle, its degree measurement can be given as 360° . Therefore, to travel half way around the world one must move 180° . The degrees of longitude increase to the east and west, away from the origin. The coordinate value for longitude is given by the degree number and the direction from the origin, i.e., 80°W or 130°E . **Note:** 180°W and 180°E share the same line of longitude.

5-11 Latitude/Longitude Computer Entry. Software cannot interpret the north/south or east/west terms used in any coordinate system. Negative numbers must be used when designating latitude coordinates south of the Equator or longitude values west of Greenwich. This means that for any location in North America the latitude coordinate will be positive and the longitude coordinate will be given as a negative number. Coordinates north of the equator and east of Greenwich will be positive. It is usually not necessary to add the positive sign (+) as the default values in most software are positive numbers. The coordinates for Niagara Fall, New York are $43^\circ 6' \text{N}$, $79^\circ 57' \text{W}$; these values would be recorded as decimal degrees in the computer as 43.1° , -79.95° . Notice that the negative sign replaces the "W" and minutes were converted to decimal degrees (see example problem below). **Important Note:** Coordinates west of Greenwich England are entered into the computer as a negative value.

5-12 Transferring Latitude/Longitude to a Map. Satellite images and aerial photographs have inherent distortions owing to the projection of the Earth's three-dimensional surface onto two-dimensional plane (paper or computer monitor). When the Latitude/Longitude coordinate system is projected onto a paper plane, there are tremendous distortions. These distortions lead to problems with area, scale, distance, and direction. To alleviate this problem cartographers have developed alternative map projections.

Problem: The Golden Gate Bridge is located at latitude $37^{\circ} 49' 11''$ N, and longitude $122^{\circ} 28' 40''$ W. Convert degrees, minutes, and seconds (known as sexagesimal system) to decimal degrees and format the value for computer entry.

Solution: The whole units of degrees will remain the same (i.e., the value will begin with 37). Minutes and seconds must be converted to degrees and added to the whole number of degrees.

Calculation: Latitude: $37^{\circ} = 37^{\circ}$
 $49' = 49'(1^{\circ}/60') = 0.82^{\circ}$
 $11'' = 11''(1'/60'')(1^{\circ}/60') = 0.003^{\circ}$
 $37^{\circ} + 0.82^{\circ} + 0.003^{\circ} = 37.82^{\circ}$
 $37^{\circ} 49' 11'' \text{ N} = 37.82^{\circ}$

Longitude: $122^{\circ} = 122^{\circ}$
 $28' = 28'(1^{\circ}/60') = 0.47^{\circ}$
 $40'' = 40''(1'/60'')(1^{\circ}/60') = 0.01^{\circ}$
 $122^{\circ} + 0.47^{\circ} + 0.01^{\circ} = 122.48^{\circ}$
 $122^{\circ} 28' 40'' \text{ W} = 122.48^{\circ}$

Answer: $37.82^{\circ}, -122.48^{\circ}$

5-13 Map Projections.

a. Map projections are attempts to render the three-dimensional surface of the earth onto a planar surface. Projections are designed to minimize distortion while preserving the accuracy of the image elements important to the user. Categories of projections are constructed from cylindrical, conic, and azimuthal planes, as well as a variety of other techniques. Each type of projection preserves and distorts different properties of a map projection. The most commonly used projections are Geographical (Lat/Lon), Universal Transverse Mercator (UTM), and individual State Plane systems. Geographic (Lat/Lon) is the projection of latitude and longitude with the use of a cylindrical plane tangent to the equator. This type of projection creates great amounts of distortion away from the poles (this explains why Greenland will appear larger than the US on some maps).

b. The best projection and datum to use will depend on the projection of accompanying data files, location of the origin of the data set, and limitations on acceptable projection distortion.

5-14 Rectification.

a. Image data commonly need to be rectified to a standard projection and datum. Rectification is a procedure that distorts the grid of image pixels onto a known projection and datum. The goal in rectification is to create a faithful representation of the scene in terms of position and radiance. Rectification is performed when the data are unprojected, needs to be reprojected, or when geometric corrections are necessary. If the analysis does not require the data to be compared or overlain onto other data, corrections and projections may not be necessary. See Figure 5-3 for an example of a rectified image.

Figure 5-3. A rectified image typically will appear skewed. The rectification correction has rubber-sheeted the pixels to their geographically correct position. This geometric correction seemingly tilts the image leaving black margins where there are no data.

b. There are two commonly used rectification methods for projecting data. Image data can be rectified by registering the data to another image that has been projected or by assigning coordinates to the unprojected image from a paper or digital map. The following sections detail these methods. A third method uses newly collected GIS reference points or in-house GIS data such as road, river, or other Civil Works GIS information.

5-15 Image to Map Rectification. Unprojected images can be warped into projections by creating a mathematical relationship between select features on an image and the same feature on a map (a USGS map for instance). The mathematical relationship is then applied to all remaining pixels, which warps the image into a projection.

5-16 Ground Control Points (GCPs). The procedure requires the use of prominent features that exist on both the map and the image. These features are commonly referred to as ground control points or GCPs. GCPs are well-defined features such as sharp bends in a river or intersections in roads or airports. Figure 5-4 illustrates the selection of GCPs in the image-to-image rectification process; this process is similar to that used in image to map rectification. The minimum number of GCPs necessary to calculate the transformation depends upon the order of the transformation. The order of transformation can be set within the software as 1st, 2nd, or 3rd order polynomial transformation. The following equation (5-1) identifies the number of GCPs required to calculate the transformation. If the minimum number is not met, an error message should inform the user to select additional points. Using more than the minimum number of GCPs is recommended.

$$\frac{(t+1)(t+2)}{2} = \text{minimum number of GCPs} \quad 5-1$$

where t = order of transformation (1st, 2nd, or 3rd).

a. To begin the procedure, locate and record the coordinate position of 10 to 12 features found on the map and in the image. Bringing a digital map into the software program will simplify coordinate determination with the use of a coordinate value tool. When using a paper map, measure feature positions as accurately as possible, and note the map coordinate system used. The type of coordinate system used must be entered into the software; this will be the projection that will be applied to the image. Once projected, the image can be easily projected into a different map projection.

b. After locating a sufficient number of features (and GCPs) on the map, find the same feature on the image and assign the coordinate value to that pixel. Zooming in to choose the precise location (pixel) will lower the error. When selecting GCPs, it is best to choose points from across the image, balancing the distribution as much as possible; this will increase the positional accuracy. Once the GCP pixels have been selected and given a coordinate value, the software will interpolate and transform the remaining pixels into position.

5-17 Positional Error. The program generates a least squares or “Root Mean Square” (RMS) estimation of the positional accuracy of the mathematical transforma-

tion. The root mean square estimates the level of error in the transformation. The estimate will not be calculated until three or four GCPs have been entered. Initial estimates will be high, and should decrease as more GCPs are added to the image. A root mean square below 1.0 is a reasonable level of accuracy. If the RMS is higher than 1.0, simply reposition GCPs with high individual errors or delete them and reselect new GCPs. With an error less than 1.0 the image is ready to be warped to the projection and saved.

a. The scene appearance of the GCP selection module may look similar to this scene capture. Each segment of the function is presented individually below.

b. This scene represents the original, unprojected data file

c. This geo-registered image is used to match sites within the unprojected data file. Projected images such as this are often available on-line.

d. GCPs are located by matching image features between the projected and unprojected image. Notice the balanced spatial distribution of the GCPs; this type of distribution lowers the projection error.

e. Unprojected data are then warped to the GCP positions. This results in a skewed image. The image is now projected onto a coordinate system and is now ready for GIS processing.

Point #	Point ID	> Color	X Input	Y Input	> Color	X Ref.	Y Ref.	Type	X Residual	Y Residual	RMS Error

f. RMS error for each GCP is recorded in a matrix spreadsheet. A total RMS error of 0.7742 is provided in the upper margin of Figure 5-4a.

Figure 5-4. GCP selection display modules.

5-18 Project Image and Save. The last procedure in rectification involves re-sampling the image using a “nearest neighbor” re-sampling technique. The software easily performs this process. Nearest neighbor re-sampling uses the value of the nearest pixel and extracts the value to the output, or re-sampled pixel. This re-sampling method preserves the digital number value (spectral value) of the original data. Additional re-sampling methods are bilinear interpolation and cubic convolution, which recalculate the spectral data. The image is projected subsequent to re-sampling, and the file is ready to be saved with a new name.

Recommendation: Naming altered data files and documenting procedures

Manipulating the data alters the original data file. It is therefore a good idea to save data files with different names after performing major alterations to the data. This practice creates reliable data backup files.

Because of the number of data files an analysis can create, it is best to clearly name the altered image files with the procedure name performed on the image (i.e., “TmSept01warped” indicates Thematic Mapper data collected September 2001, warped by user). Be sure to document your procedures and parameters used in a journal or a text file. Include the name of the altered file, changes applied to the data, the date, and other useful information.

5-19 Image to Image Rectification.

a. Images can also be rectified to a second projected digital image. The procedure is similar to that performed in image to map rectification. Simply locate common, identifiable features in both images, match the locations, and assign GCPs. Adjust GCPs until RMS error is less than 1.0. Enter the coordinate system that will be used and designate a re-sampling method (Figure 5-4).

b. Rectified images can easily be converted from one coordinate system to another. Projected images can readily be superimposed onto other projected data and used for georeferencing image features.

5-20 Image Enhancement. The major advantage of remote sensing data lies in the ability to visually evaluate the data for overall interpretation. An accurate visual interpretation may require modification of the output brightness of a pixel in an effort to improve image quality. Here are a number of methods used in image enhancement. This paragraph examines the operations of 1) contrast enhancement, 2) band ratio, 3) spatial filtering, and 4) principle components. The type of enhancement performed will depend on the appearance of the original scene and the goal of the interpretation.

a. Image Enhancement #1: Contrast Enhancement.

(1) *Raw Image Data.* Raw satellite data are stored as multiple levels of brightness known as the digital number (DN). Paragraph 2-7*a* explained the relationship between the number of brightness levels and the size of the data storage. Data stored in an 8-bit data format maintain 256 levels of brightness. This means that the range in brightness will be 0 to 255; zero is assigned the lowest brightness level (black in gray- and color-scale images), while 255 is assigned the highest brightness value (white in gray scale or 100% of the pigment in a color scale). The list below summarizes the brightness ranges in a gray scale image.

0	=	black
50	=	dark gray
150	=	medium gray
200	=	light gray
255	=	white

(*a*) When a satellite image is projected, the direct one-to-one assignment of gray scale brightness to digital number values in the data set may not provide the best visual display (Figures 5-5 and 5-6). This will happen when a number of pixel values are clustered together. For instance, if 80% of the pixels displayed DNs ranging from 50–95, the image would appear dark with little contrast.

Figure 5-5. A linear stretch involves identifying the minimum and maximum brightness values in the image histogram and applying a transformation to stretch this range to fill the full range across 0 to 255.

Figure 5-6. Contrast in an image before (left) and after (right) a linear contrast stretch. Taken from http://rst.gsfc.nasa.gov/Sect1/Sect1_12a.html.

(b) The raw data can be reassigned in a number of ways to improve the contrast needed to visually interpret the data. The technique of reassigning the pixel DN value is known as the image enhancement process. Image enhancement adds contrast to the data by stretching clustered DNs across the 0–255 range. If only a small part of the DN range is of interest, image enhancement can stretch those values and compress the end values to suppress their contrast. If a number of DNs are clustered on the 255 end of the range,

it is possible that a number of the pixels have DN's greater than 256. An image enhancement will decompress these values, thereby increasing their contrast.

Data Analysis

Histograms

Image processing software can chart the distribution of digital number values within a scene. The distribution of the brightness values is displayed as a histogram chart. The horizontal axis shows the spread of the digital numbers from 0 to the maximum DN value in the data set. The vertical axis shows the frequency or how many pixels in the scene each value has (Figure 5-7). The histogram allows an analyst to quickly access the type of distribution maintained by the data. Types of distribution may be normal, bimodal, or skewed (Figure 5-7). Histograms are particularly useful when images are enhanced.

Lookup Tables

A lookup table (LUT) graphs the intensity of the input pixel value relative to the output brightness observed on the screen. The curve does not provide information about the frequency of brightness, instead it provides information regarding the range associated with the brightness levels. An image enhancement can be modeled on a lookup table to better evaluate the relationship between the unaltered raw data and the adjusted display data.

Scatter plots

The correlation between bands can be seen in scatter plots generated by the software. The scatter plots graph the digital number value of one band relative to another (Figure 5-8). Bands that are highly correlated will produce plots with a linear relationship and little deviation from the line. Bands that are not well correlated will lack a linear relationship. Digital number values will cluster or span the chart randomly. Scatter plots allow for a quick assessment of the usefulness of particular band combinations.

Figure 5-7. Pixel population and distribution across the 0 to 255 digital number range. All three plots show the pixel distribution before and after a linear stretch function (white denotes pre-stretch distribution and colored elements denote stretched pixel distribution). The stretched histogram shows gaps between the single values due to the discrete number of pixel values in the data set. The top histogram (red) has a bimodal distribution. The middle (green) maintains a skewed distribution, while the last histogram (blue) reveals a normal distribution. The solid black line superimposed in each image indicates the maximum and minimum DN value that is stretched across the entire range. Notice the straight lines that join the linear segment. Image taken from Prospect (2002 and 2003).

Figure 5-8. Landsat TM band 345 RGB color composite with accompanying image scatter plots. The scatter plots map band 3 relative to bands 4 and 5 onto a feature space graph. The data points in the plot are color coded to display pixel population. The table provides the pixel count for five image features in band 3, 4, and 5. A is agricultural land, B is deep (partially clear) water, C is sediment laden water, D is undeveloped land, E fallow fields. Image developed for Prospect (2002 and 2003).

(2) *Enhancing Pixel Digital Number Values.* Images can enhance or stretch the visual display of an image by setting up a different relationship between the DN and the brightness level. The enhancement relationship created will depend on the distribution of pixel DN values and which features need enhancement. The enhancement can be applied to both gray- and color-scale images.

(3) *Contrast Enhancement Techniques.* The histogram chart and lookup table are useful tools in image enhancement. Enhancement stretching involves a variety of techniques, including contrast stretching, histogram equalization, logarithmic enhancement, and manual enhancement. These methods assume the image has a full range of intensity (from 0–255 in 8-bit data) to display the maximum contrast.

(4) *Linear Contrast Stretching.* Contrast stretching takes an image with clustered intensity values and stretches its values linearly over the 0–255 range. Pixels in a very

bright scene will have a histogram with high intensity values, while a dark scene will have low intensity values (Figure 5-9). The low contrast that results from this type of DN distribution can be adjusted with contrast stretching, a linear enhancement function performed by image processing software. The method can be monitored with the use of a histogram display generated by the program.

Figure 5-9. Unenhanced satellite data on left. After a default stretch, image contrast is increased as the digital number values are distributed over the 0–255 color range. The resulting scene (shown on the right) has a higher contrast.

(a) Contrast stretching allocates the minimum and maximum input values to 0 and 255, respectively. The process assigns a gray level 0 to a selected low DN value, chosen by the user. All DNs smaller than this value are assigned 0 as well, grouping the low input values together. Gray level 255 is similarly assigned to a selected high DN value and all higher DN values. Intermediate gray levels are assigned to intermediate DN values proportionally. The resulting graph looks like a straight line (shown in Figure 5-7 as the black solid-line plot superimposed onto the three DN histograms), while the corresponding histogram will distribute values across the range, leaving an increase to the image contrast (Figure 5-9). The stretched histogram shows gaps between the single values due to the discrete number of pixel values in the data set (Figure 5-7). The proportional brightness gives a more accurate appearance to the image data, and will better accommodate visual interpretation.

(b) The linear enhancement can be greatly affected by a random error that is particularly high or low in brightness values. For this reason, a non-linear stretch is sometimes preferred. In non-linear stretches, such as histogram equalization and logarithmic enhancement, brightness values are reassigned using an algorithm that exaggerates contrast in the range of brightness values most common in that image.

(5) *Histogram Equalization*. Low contrast can also occur when values are spread across the entire range. The low contrast is a result of tight clustering of pixels in one area (Figure 5-10a). Because some pixel values span the intensity range it is not possible to apply the contrast linear stretch. In Figure 5-10a, the high peak on the low intensity end of the histogram indicates that a narrow range of DN values is used by a large number of pixels. This explains why the image appears dark despite the span of values across the full 0–255 range.

(a) Histogram equalization evenly distributes the pixel values over the entire intensity range (see steps below). The pixels in a scene are numerically arranged according to their DN values and divided into 255 equal-sized groups. The lowest level is assigned a gray level of zero, the next group is assigned DN 1, ..., the highest group is assigned gray level 255. If a single DN value has more pixels than a group, gray levels will be skipped. This produces gaps in the histogram distribution. The resultant shape of the graph will depend on the frequency of the scene.

(b) This method generally reduces the peaks in the histogram, resulting in a flatter or lower curve (Figure 5-10b). The histogram equalization method tends to enhance distinctions within the darkest and brightest pixels, sacrificing distinctions in mid-gray. This process will result in an overall increase in image contrast (Figure 5-10b).

(6) *Logarithmic Enhancement*. Another type of enhancement stretch uses a logarithmic algorithm. This type of enhancement distinguishes lower DN values. The high intensity values are grouped together, which sacrifices the distinction of pixels with higher DN.

(7) *Manual Enhancement*. Some software packages will allow users to define an arbitrary enhancement. This can be done graphically or numerically. Manually adjusting the enhancement allows the user to reduce the signal noise in addition to reducing the contrast in unimportant pixels. **Note:** The processes described above do not alter the spectral radiance of the pixel raw data. Instead, the output display of the radiance is modified by a computed algorithm to improve image quality.

b. Image Enhancement #2: Band Arithmetic

(1) *Band Arithmetic*. Spectral band data values can be combined using arithmetic to create a new “band.” The digital number values can be summed, subtracted, multiplied, and divided (see equations 5-1 and 5-2). Image software easily performs these operations. This section will review only those arithmetic processes that involve the division or ratio of digital band data.

(2) *Band Ratio*. Band ratio is a commonly used band arithmetic method in which one spectral band is proportioned with another spectral band. This simple method reduces the effects of shadowing caused by topography, highlights particular image elements, and accentuates temporal differences (Figure 5-11).

a. Image and its corresponding DN histogram show that the majority of pixels are clustered together (centering approximately on DN value of 100).

b. After histogram equalization stretch the pixels are reassigned new values and spread out across the entire value range. The data maximum is subdued while the histogram leading and trailing edges are amplified, the resulting image has an overall increase in contrast.

Figure 5-10. Landsat image of Denver area.

Landsat bands 3, 2, 1

Band ratio 3/1 highlights hematite

Band ratio 1/7 highlights aluminum ore

Band ratio 7/5 highlights clays

Band ratio 4/2 highlights biomass

Figure 5-11. NASA Landsat images from top to bottom: Color composite bands 3, 2, 1, band ratio 3/1 highlights iron oxide minerals, band ratios 7/5 and 1/7 reveals the presence of water in minerals—appropriate for mapping clay minerals or aluminum ore, and band ratio 4/2 allows for biomass determination.

(3) *Shadow Removal from Data.* The effect of shadowing is typically caused by a combination of sun angle and large topographic features (i.e., shadows of mountains). Table 5-1 lists the pixel digital number values for radiance measured from two different objects for two bands (arbitrarily chosen) under differing lighting conditions. Pixel data representing the radiance reflecting off deciduous trees (trees that lose their leaves annually) is consistently higher for non-shadowed objects. This holds true as shadowing effectively lowers the pixel radiance. When the ratio of the two bands is taken (or divided by one another) the resultant ratio value is not influenced by the effects of shadowing (see Table 5-1). The band ratio therefore creates a more reliable data set.

Table 5-1
Effects of shadowing

Tree type	Light conditions	Band A (DN)	Band B (DN)	Band A/B (ratio) (DN)
Deciduous Trees	In sunlight	48	50	0.96
	In shadow	18	19	0.95
Coniferous Trees	In sunlight	31	45	0.69
	In shadow	11	16	0.69

(4) *Emphasize Image Elements.* A number of ratios have been empirically developed and can highlight many aspects of a scene. Listed below are only a few common band ratios and their uses. When choosing bands for this method, it is best to consider bands that are poorly correlated. A greater amount of information can be extracted from ratios with bands that are covariant.

- B3/B1 – iron oxide
- B3/B4 – vegetation
- B4/B2 – vegetation biomass
- B4/B3 – known as the RVI (Ratio Vegetation Index)
- B5/B2 – separates land from water
- B7/B5 – hydrous minerals
- B1/B7 – aluminum hydroxides
- B5/B3 – clay minerals

(5) *Temporal Differences.* Band ratio can also be used to detect temporal changes in a scene. For instance, if a project requires the monitoring of vegetation change in a scene, a ratio of band 3 from image data collected at different times can be used. The newly created band file may have a name such as “Band3’Oct.98/Ban3’Oct.02.” When the new band is loaded, the resulting ratio will highlight areas of change; these pixels will appear brighter. For areas with no change, the resulting pixel values will be low and the resulting pixel will appear gray.

(a) One advantage of the ratio function lies in its ability to not only filter out the effects of shadowing but also the effects attributable to differences in sun angle. The sun angle may change from image to image for a particular scene. The sun angle is controlled by the time of day the data were collected as well as the time of year (seasonal effects). Processing images collected under different sun angle conditions may be un-

avoidable. Again, a ratio of the bands of interest will limit shadowing and sun angle effects. It is therefore possible to perform a temporal analysis on data collected at different times of the day or even at different seasons.

(b) A disadvantage of using band ratio is the emphasis that is placed on noise in the image. This can be reduced, however, by applying a spatial filter before employing the ratio function; this will reduce the signal noise. See Paragraph 5-20c.

(6) *Create a New Band with the Ratio Data.* Most software permits the user to perform a band ratio function. The band ratio function converts the ratio value to a meaningful digital number (using the 256 levels of brightness for 8-bit data). The ratio can then be saved as a new band and loaded onto a gray scale image or as a single band in a color composite.

(7) *Other Types of Ratios and Band Arithmetic.* There are a handful of ratios that highlight vegetation in a scene. The NDVI (Normalized Difference Vegetation Index; equations 5-1 and 5-2) is known as the “vegetation index”; its values range from -1 to 1.

$$\text{NDVI} = \frac{\text{NIR} - \text{red}}{\text{NIR} + \text{red}} \quad (5-1)$$

where NDVI is the normalized difference vegetation index, NIR is the near infrared, and red is the band of wavelengths coinciding with the red region of the visible portion of the spectrum. For Landsat TM data this equation is equivalent to:

$$\text{NDVI} = \frac{\text{Band 4} - \text{Band 3}}{\text{Band 4} + \text{Band 3}} \quad (5-2)$$

In addition to the NDVI, there is also IPVI (Infrared Percentage Vegetation Index), DVI (Difference Vegetation Index), and PVI (Perpendicular Vegetation Index) just to name a few. Variation in vegetation indices stem from the need for faster computations and the isolation of particular features. Figure 5-12 illustrates the NDVI.

Figure 5-12. Top: True color CAMIS image. Bottom: NDVI mask isolating vegetated pixels. This mask will be useful during the classification process, which will subsequently classify only the vegetation in the scene while disregarding water and urban features. Taken from Campbell (2003).

c. *Image Enhancement #3: Spatial Filters.* It is occasionally advantageous to reduce the detail or exaggerate particular features in an image. This can be done by a convolution method creating an altered or “filtered” output image data file. Numerous spatial filters have been developed and can be automated within software programs. A user can also develop his or her own spatial filter to control the output data set. Presented below is a short introduction to the method of convolution and a few commonly used spatial filters.

(1) *Spatial Frequency.* Spatial frequency describes the pattern of digital values observed across an image. Images with little contrast (very bright or very dark) have zero spatial frequency. Images with a gradational change from bright to dark pixel values have low spatial frequency; while those with large contrast (black and white) are said to have high spatial frequency. Images can be altered from a high to low spatial frequency with the use of convolution methods.

(2) *Convolution.*

(a) Convolution is a mathematical operation used to change the spatial frequency of digital data in the image. It is used to suppress noise in the data or to exaggerate features of interest. The operation is performed with the use of a spatial kernel. A kernel is an array of digital number values that form a matrix with odd numbered rows and columns (Table 5-2). The kernel values, or coefficients, are used to average each pixel relative to its neighbor across the image. The output data set will represent the averaging effect of the kernel coefficients. As a spatial filter, convolution can smooth or blur images, thereby reducing image noise. In feature detection, such as an edge enhancement, convolution works to exaggerate the spatial frequency in the image. Kernels can be reapplied to an image to further smooth or exaggerate spatial frequency.

(b) Low pass filters apply a small gain to the input data (Table 5-2a). The resulting output data will decrease the spatial frequency by de-emphasizing relatively bright pixels. Two types of low pass filters are the simple mean and center-weighted mean methods (Table 5-2a and b). The resultant image will appear blurred. Alternatively, high pass frequency filters (Table 5-2c) increase image spatial frequency. These types of filters exaggerate edges without reducing image details (an advantage over the Laplacian filter discussed below).

(2) *Laplacian or Edge Detection Filter.*

(a) The Laplacian filter detects discrete changes in spectral frequency and is used for highlighting edge features in images. This type of filter works well for delineating linear features, such as geologic strata or urban structures. The Laplacian is calculated by an edge enhancement kernel (Table 5-2d and e); the middle number in the matrix is much higher or lower than the adjacent coefficients. This type of kernel is sensitive to noise and the resulting output data will exaggerate the pixel noise. A smoothing convolution filter can be applied to the image in advance to reduce the edge filter's sensitivity to data noise.

The Convolution Method

Convolution is carried out by overlaying a kernel onto the pixel image and centering its middle value over the pixel of interest. The kernel is first placed above the pixel located at the top left corner of the image and moved from top to bottom, left to right. Each kernel position will create an output pixel value, which is calculated by multiplying each input pixel value with the kernel coefficient above it. The product of the input data and kernel is then averaged over the array (sum of the product divided by the number of pixels evaluated); the output value is assigned this average. The kernel then moves to the next pixel, always using the original input data set for calculating averages. Go to <http://www.cla.sc.edu/geog/rslab/Rsc/rsc-frames.html> for an in-depth description and examples of the convolution method.

The pixels at the edges create a problem owing to the absence of neighboring pixels. This problem can be solved by inventing input data values. A simpler solution for this problem is to clip the bottom row and right column of pixels at the margin.

(b) The Laplacian filter measures the changes in spectral frequency or pixel intensity. In areas of the image where the pixel intensity is constant, the filter assigns a digital number value of 0. Where there are changes in intensity, the filter assigns a positive or negative value to designate an increase or decrease in the intensity change. The resulting image will appear black and white, with white pixels defining the areas of changes in intensity.

Table 5-2

Variety in 9-Matrix Kernel Filters Used in a Convolution Enhancement. Each graphic shows a kernel, an example of raw DN data array, and the resultant enhanced data array. See <http://www.cee.hw.ac.uk/hipr/html/filtops.html> for further information on kernels and the filtering methods.

d. *Image Enhancement #4: Principle Components.* The principle component analysis (PCA) is a technique that transforms the pixel brightness values. This transformation compresses the data by drawing out maximum covariance and removes correlated elements. The resulting data will contain new, uncorrelated data that can be later used in classification techniques.

(1) *Band Correlation.* Spectral bands display a range of correlation from one band to another. This correlation is easily viewed by bringing up a scatter plot of the digital data and plotting, for instance, band 1 vs. band 2. Many bands share elements of information, particularly bands that are spectrally close to one another, such as band 1 and 2. For bands that are highly correlated, it is possible to predict the brightness outcome of one band with the data of the other (Figure 5-13). Therefore, bands that are well correlated may not be of use when attempting to isolate spectrally similar objects.

Figure 5-13. Indian IRS-1D image and accompanying spectral plot. Representative pixel points for four image elements (fluvial sediment in a braided channel, water, agriculture, and forest) are plotted for each band. Plot illustrates the ease by which each element can be spectrally separated. For example, water is easily distinguishable from the other elements in band 2.

(2) *Principle Component Transformation.* The principle component method extracts the small amount of variance that may exist between two highly correlated bands and effectively removes redundancy in the data. This is done by “transforming” the major vertical and horizontal axes. The transformation is accomplished by rotating the horizontal axis so that it is parallel to a least squares regression line that estimates the data. This transformed axis is known as PC_1 , or Principle Component 1. A second axis, PC_2 , is drawn perpendicular to PC_1 , and its origin is placed at the center of the PC_1 range (Figure 5-14). The digital number values are then re-plotted on the newly transformed axes. This transformation will result in data with a broader range of values. The data can be saved as a separate file and loaded as an image for analysis.

Figure 5-14. Plot illustrates the spectral variance between two bands, A and B. PC_1 is the line that captures the mean of the data set. PC_2 is orthogonal to PC_1 . PC_1 and PC_2 become the new horizontal and vertical axis; brightness values are redrawn onto the PC_1 and PC_2 scale.

c. Transformation Series (PC_1 , PC_2 , PC_3 , PC_4 , PC_5 , etc.). The process of transforming the axis to fit the maximum variance in the data can be performed in succession on the same data set. Each successive axis rotation creates a new principal component axis; a series of transformations can then be saved as individual files. Band correlation is greatly reduced in the first PC transformation, 90% of the variance between the bands will be isolated by PC_1 . Each principle component transformation extracts less and less variance, PC_2 , for instance, isolates 5% of the variance, and PC_3 will extract 3% of the variance, and so on (Figure 5-15). Once PC_1 and PC_2 have been processed, approximately 95% of the variance within the bands will be extracted. In many cases, it is not useful to extract the variance beyond the third principle component. Because the principle component function reduces the size of the original data file, it functions as a pre-processing tool and better prepares the data for image classification. The de-correlation of band data in the principle component analysis is mathematically complex. It linearly

transforms the data using a form of factor analysis (eigen value and eigen vector matrix). For a complete discussion of the technique see Jensen (1996).

Figure 5-15. PC-1 contains most of the variance in the data. Each successive PC-transformation isolates less and less variation in the data. Taken from <http://rst.gsfc.nasa.gov/start.html>.

d. Image Classification. Raw digital data can be sorted and categorized into thematic maps. Thematic maps allow the analyst to simplify the image view by assigning pixels into classes with similar spectral values (Figure 5-16). The process of categorizing pixels into broader groups is known as image classification. The advantage of classification is it allows for cost-effective mapping of the spatial distribution of similar objects (i.e., tree types in forest scenes); a subsequent statistical analysis can then follow. Thematic maps are developed by two types of classifications, supervised and unsupervised. Both types of classification rely on two primary methods, training and classifying. Training is the designation of representative pixels that define the spectral signature of the object class. Training site or training class is the term given to a group of training pixels. Classifying procedures use the training class to classify the remaining pixels in the image.

Figure 5-16. Landsat image (left) and its corresponding thematic map (right) with 17 thematic classes. The black zigzag at bottom of image is the result of shortened flight line over-lap. (Campbell, 2003).

(1) *Supervised Classification.* Supervised classification requires some knowledge about the scene, such as specific vegetative species. Ground truth (field data), or data from aerial photographs or maps can all be used to identify objects in the scene.

(2) *Steps Required for Supervised Classification.*

(a) Firstly, acquire satellite data and accompanying metadata. Look for information regarding platform, projection, resolution, coverage, and, importantly, meteorological conditions before and during data acquisition.

(b) Secondly, chose the surface types to be mapped. Collect ground truth data with positional accuracy (GPS). These data are used to develop the training classes for the discriminant analysis. Ideally, it is best to time the ground truth data collection to coincide with the satellite passing overhead.

(c) Thirdly, begin the classification by performing image post-processing techniques (corrections, image mosaics, and enhancements). Select pixels in the image that are representative (and homogeneous) of the object. If GPS field data were collected, geo-register the GPS field plots onto the imagery and define the image training sites by outlining the GPS polygons. A training class contains the sum of points (pixels) or polygons (clusters of pixels) (see Figures 5-17 and 5-18). View the spectral histogram to inspect the homogeneity of the training classes for each spectral band. Assign a color to represent each class and save the training site as a separate file. Lastly, extract the re-

maining image pixels into the designated classes by using a discriminate analysis routine (discussed below).

Figure 5-17. Landsat 7 ETM image of central Australia (4, 3, 2 RGB). Linear features in the upper portion of the scene are sand dunes. Training data are selected with a selection tool (note the red enclosure). A similar process was performed on data from Figure 5-16 (the DN values for figure 5-16 are presented in Figure 5-18).

Figure 5-18. Classification training data of 35 landscape classification features. “Training” provides the pixel count after training selection; classification provides the image pixel count after a classification algorithm is performed. This data set accompanies Figure 5-16, the classified image. (Campbell, 2003).

(3) *Classification Algorithms.* Image pixels are extracted into the designated classes by a computed discriminant analysis. The three types of discriminant analysis algorithms are: minimum mean distance, maximum likelihood, and parallelepiped. All use brightness plots to establish the relationship between individual pixels and the training class (or training site).

(a) *Minimum Mean Distance.* Minimum distance to the mean is a simple computation that classifies pixels based on their distance from the mean of the training class.

It is determined by plotting the pixel brightness and calculating its Euclidean distance (using the Pythagorean theorem) to the unassigned pixel. Pixels are assigned to the training class for which it has a minimum distance. The user designates a minimum distance threshold for an acceptable distance; pixels with distance values above the designated threshold will be classified as unknown.

(b) *Parallelepiped*. In a parallelepiped computation, unassigned pixels are grouped into a class when their brightness values fall within a range of the training mean. An acceptable digital number range is established by setting the maximum and minimum class range to plus and minus the standard deviation from the training mean. The pixel brightness value simply needs to fall within the class range, and is not based on its Euclidean distance. It is possible for a pixel to have a brightness value close to a class and not fall within its acceptable range. Likewise, a pixel may be far from a class mean, but fall within the range and therefore be grouped with that class. This type of classification can create training site overlap, causing some pixels to be misclassified.

(c) *Maximum Likelihood*. Maximum Likelihood is computationally complex. It establishes the variance and covariance about the mean of the training classes. This algorithm then statistically calculates the probability of an unassigned pixel belonging to each class. The pixel is then assigned to the class for which it has the highest probability. Figure 5-19 visually illustrates the differences between these supervised classification methods.

Figure 5-19. From left to right, minimum mean distance, parallelepiped, and maximum likelihood. Courtesy of the Department of Geosciences at Murray State University.

(4) *Assessing Error*. Accuracy can be qualitatively determined by an error matrix (Table 5-3). The matrix establishes the level of errors due to omission (exclusion error), commission (inclusion error), and can tabulate an overall total accuracy. The error matrix lists the number of pixels found within a given class. The rows in Table 5-2 list the pixels classified by the image software. The columns list the number of pixels in the reference data (or reported from field data). Omission error calculates the probability of

a pixel being accurately classified; it is a comparison to a reference. Commission determines the probability that a pixel represents the class for which it has been assigned. The total accuracy is measured by calculating the proportion correctly classified pixel relative to the total tested number of pixels (Total = total correct/total tested).

Table 5-3
Omission and Commission Accuracy Assessment Matrix. Taken from Jensen (1996).

Reference Data						
Classification	Residential	Commercial	Wetland	Forest	Water	Raw Total
Residential	70	5	0	13	0	88
Commercial	3	55	0	0	0	58
Wetland	0	0	99	0	0	99
Forest	0	0	4	37	0	41
Water	0	0	0	0	121	121
Column Total	73	60	103	50	121	407
Overall Accuracy = 382/407=93.86%						

Producer's Accuracy (measure of omission error)

Residential= $70/73 = 96-4\%$ omission error
Commercial= $55/60 = 92-8\%$ omission error
Wetland= $99/103 = 96-4\%$ omission error
Forest= $37/50 = 74-26\%$ omission error
Water= $121/121 = 100-0\%$ omission error

User's Accuracy (measure of commission error)

Residential= $70/88 = 80-20\%$ omission error
Commercial= $55/58 = 95-5\%$ omission error
Wetland= $99/99 = 100-0\%$ omission error
Forest= $37/41 = 90-10\%$ omission error
Water= $121/121 = 100-0\%$ omission error

Example error matrix taken from Jensen (1986). Data are the result of an accuracy assessment of Landsat TM data.

Classification method summary

Image classification uses the brightness values in one or more spectral bands, and classifies each pixel based on its spectral information

The goal in classification is to assign remaining pixels in the image to a designated class such as water, forest, agriculture, urban, etc.

The resulting **classified** image is composed of a collection of pixels, color-coded to represent a particular theme. The overall process then leads to the creation of a thematic map to be used to visually and statistically assess the scene.

(5) *Unsupervised Classification.* Unsupervised classification does not require prior knowledge. This type of classification relies on a computed algorithm that clusters pixels based on their inherent spectral similarities.

(a) *Steps Required for Unsupervised Classification.* The user designates 1) the number of classes, 2) the maximum number of iterations, 3) the maximum number of times a pixel can be moved from one cluster to another with each iteration, 4) the minimum distance from the mean, and 5) the maximum standard deviation allowable. The program will iterate and recalculate the cluster data until it reaches the iteration threshold designated by the user. Each cluster is chosen by the algorithm and will be evenly distributed across the spectral range maintained by the pixels in the scene. The resulting classification image (Figure 5-20) will approximate that which would be produced with the use of a minimum mean distance classifier (see above, “classification algorithm”). When the iteration threshold has been reached the program may require you to rename and save the data clusters as a new file. The display will automatically assign a color to each class; it is possible to alter the color assignments to match an existing color scheme (i.e., blue = water, green = vegetation, red = urban) after the file has been saved. In the unsupervised classification process, one class of pixels may be mixed and assigned the color black. These pixels represent values that did not meet the requirements set by the user. This may be attributable to spectral “mixing” represented by the pixel.

(b) *Advantages of Using Unsupervised Classification.* Unsupervised classification is useful for evaluating areas where you have little or no knowledge of the site. It can be used as an initial tool to assess the scene prior to a supervised classification. Unlike supervised classification, which requires the user to hand select the training sites, the unsupervised classification is unbiased in its geographical assessment of pixels.

(c) *Disadvantages of Using Unsupervised Classification.* The lack of information about a scene can make the necessary algorithm decisions difficult. For instance, without knowledge of a scene, a user may have to experiment with the number of spectral clusters to assign. Each iteration is time consuming and the final image may be difficult to interpret (particularly if there is a large number of unidentified pixels such as those in Figure 5-19). The unsupervised classification is not sensitive to covariation and variations in the spectral signature to objects. The algorithm may mistakenly separate pixels with slightly different spectral values and assign them to a unique cluster when they, in fact, represent a spectral continuum of a group of similar objects.

(6) *Evaluating Pixel Classes.* The advantages of both the supervised and unsupervised classification lie in the ease with which programs can perform statistical analysis. Once pixel classes have been assigned, it is possible to list the exact number of pixels in each representative class (Figure 5-17, classified column). As the size of each pixel is known from the metadata, the metric area of each class can be quickly calculated. For example, you can very quickly deter-

mine the percentage of fallow field area versus productive field area in an agricultural scene.

Figure 5-20. Unsupervised and supervised classification of a clay-mine (upper center, bright green pixels) imaged with HyMap hyperspectral data. Images courtesy of Dr. Brigitte Martini at the Earth Sciences Department, University of California, Santa Cruz, CA. Go to <http://www.es.ucsc.edu/~hyperwww/chevron/whatisrs5.html> for details on the image.

e. Image Mosaics, Image subsets, and Multiple Image Analysis.

(1) *Image Mosaics.* It is not uncommon for a study area to include areas beyond the range of an individual scene. In such a case, it will be necessary to collect adjacent scenes and mosaic or piece them together (Figures 5-21–5-23). It is preferable to choose scenes with data collected during the same season or general time frame and under similar weather conditions. Images can only be properly pieced together if their data are registered in the same projection and datum. It will be important to assess the registration of all images before attaching the scenes together. If any of the images are misregistered, this will lead to gaps in the image or it will create pixel overlay.

(2) *Image Mosaic and Image Subset*. The mosaic process is a common feature in image processing programs. It is best to perform image enhancements prior to piecing separate scenes together. Once the images are pieced together, the resulting image may be large and include areas outside the study region. It is good practice to take a subset of this larger scene to reduce the size of the image file. This will make subsequent image processing faster. To do this, use the clip or subset function in a software program. The clip function will need to know the corner coordinates of the subset (usually the upper left and lower right). Some software may require this procedure to be repeated for each individual band of data. The subset should be named and saved as a separate file or files. **Note:** An image subset may also be required if the margins of a newly registered scene are skewed, or if the study only requires a small portion of one scene. Reduction of the spatial dimensions of a scene reduces the image file size, simplifies image classification, and prepares the image for map production.

Example: Calculate the percentage of land cover types for a classification performed on a Landsat TM image with a spatial resolution of 30 m using a supervised maximum likelihood classification with a 3.0 standard deviation.

Solution: Calculate the percentage based on the total

Percent Calculation

Class	Number of class pixels	Percentage
Water	16,903	$(16,903/413,469) \times 100 = 4.1\%$
Forest:	368,641	$(368,641/413,469) \times 100 = 89.1\%$
Wetlands	6,736	$(6,736/413,469) \times 100 = 1.6\%$
Agriculture	13,853	$(13,853/413,469) \times 100 = 3.4\%$
Urban	6,255	$(6,255/413,469) \times 100 = 1.5\%$
Unknown	1081	$(1081/413,469) \times 100 = 0.3\%$
Total	413,469	$(413,469/413,469) \times 100 = 100\%$

Maximum likelihood is a superior classifier and training classes are well defined. This is evident in the low number of pixels in the unknown class.

Area can be calculated using the number of pixels in a class and multiplying it by the ground dimensions of the pixel. For example the number of square meters and hectares in the wetland class of this example is:

Wetlands	$6,736 \times (30\text{m})^2 = 6.1 \times 10^6 \text{ m}^2$	606.24 ha
----------	---	-----------

This last step is often not necessary as many software programs automatically calculate the hectares for each class.

Figure 5-21. Multiple Landsat TM images, shown on the left (some sub-scenes are not shown here) were pieced together to create the larger mosaic image on the right. The seams within the mosaic image (right) are virtually invisible, an indication of the accuracy of the projection. Taken from Prospect (2002 and 2003).

Figure 5-22. Multi-image mosaic of Western United States centered on the state of Utah. Mosaic seams are invisible in this scene, an indication of good radiometric and geometric corrections. The skewed and curved margins are an artifact of the rectification and mosaic process. Taken from http://www.jpl.nasa.gov/images/earth/usa/misr_020602_2.html.

Figure 5-23. Landsat 7 Image of the Boston, Massachusetts area. Image on the right shows red box outlining the boundaries of the subset scene on the left. Taken from <http://landsat.gsfc.nasa.gov/education/l7downloads/index.html>.

(3) *Multiple-image Temporal Analysis.* It is possible to combine bands from different images or data sets. This allows a user to perform a change detection analysis. The process of “layering” multi-temporal data involves loading a composite of bands from different images of the same scene. For example, a study assessing urban development in a forested area would benefit from examining a band combination that included band 3 data in the red plane, and band 3 data of a later image in the green plane. If the spectral signature of the scene has changed and is detectable within the resolution of the data, then changes in the scene will be highlighted. This image can then be classified and the areas of change can be statistically assessed. To perform this task accurately, it is important that both images are registered properly. Misregistration will lead to an offset in the image, which leaves brightly colored lines of pixels. Be sure to choose images whose data were collected under similar conditions, such as the same season, time of day, and prevailing weather, i.e., minimum cloud cover.

f. Remote Sensing and Geospatial Information. Remote sensing data are easily integrated with other digital data, such as vector data used in a GIS (Geographical Information System). Vector data can be incorporated into a raster satellite image by overlaying the data onto an image scene. Conversely, a raster image can be saved as a .jpeg or .tiff file and exported to a vector software processing program. Remote sensing data files can provide land cover and use information as well as digital elevation models (DEMs), and a number of geo-physical and biophysical parameters. Satellite images coupled with GIS data can be used to create original maps. The use of remote sensing in this type of application can drastically cut costs of GIS database development. It also provides data for inaccessible areas.

(1) *Digital Orthoquadrangle (DOQs).* A digital orthoquadrangle (DOQ) is a digital image of an aerial photograph that has had ground relief removed and is

geometrically corrected. The removal of ground relief adds to the accuracy measurement of distances on the ground. DOQs are available over the internet through the USGS or state level natural resources and environmental agencies. They come in black and white and color infrared. These digital aerial photographs come in a variety of scales and resolutions (often 1-m GSD). Due to the ortho-correction process, DOQs are typically in UTM, Geographic, or State Plane Projection. The images typically have 50 to 300 m overlap. This overlap simplifies the mosaic process. DOQs work well in combination with GIS data and may aid in the identification of objects in a satellite scene. It is possible to link a DOQ with a satellite image and a one-to-one comparison can be made between a pixel on the satellite image and the same geographic point on the DOQ.

(2) *Digital Elevation Models (DEM)*. A Digital Elevation Model (DEM) is a digital display of cartographic elements, particularly topographic features. DEMs utilize two primary types of data, DTM (digital terrain model) or DSM (digital surface model). The DTM represents elevation points of the ground, while DSM is the elevation of points at the surface, which includes the top of buildings and trees, in addition to terrain. The DEM incorporates the elevation data and projects it relative to a coordinate reference point. (See <http://www.ipf.tuwien.ac.at/fr/buildings/diss/node27.html> for more information on DEM, DTM, and DSMs.

(3) *DEM Generation*. Elevation measurements are sampled at regular intervals to form an array of elevation points within the DEM. The elevation data are then converted to brightness values and can be displayed as a gray scale image (Figure 5-24). The model can be viewed in image processing software and superimposed onto satellite image data. The resulting image will appear as a “three-dimensional” view of the image data.

(a) DEMs come in a variety of scales and resolutions. Be sure to check the date and accuracy of the DEM file. DEMs produced before 2001 have as much as 30 m of horizontal error. As with other files, the DEM must be well registered and in the same projection and datum as other files in the scene. Check the metadata accompanying the data to verify the projection.

(b) The primary source of DEM data is digital USGS topographic maps and not satellite data. Spaceborne elevation data will be more readily available with the processing and public release of the Shuttle Radar Topography Mission (SRTM) data. Some of this data is currently available through the Jet Propulsion Laboratory (<http://www.jpl.nasa.gov/srtm/>) and USGS EROS Data Center (<http://srtm.usgs.gov/index.html>).

Figure 5-24. Digital elevation model (DEM). The brightness values in this image represent elevation data. Dark pixels correspond to low elevations while the brightest pixels represent higher elevations. Taken from the NASA tutorial at http://rst.gsfc.nasa.gov/Sect11/Sect11_5.html.

(c) DEMs can be created for a study site with the use of a high resolution raster topographic map. The method involved in creating a DEM is fairly advanced; see <http://spatialnews.geocomm.com/features/childs3/> for information on getting starting in DEM production.

(4) *Advanced Methods in Image Processing.* Remote sensing software facilitates a number of advanced image processing methods. These advanced methods include the processing of hyperspectral data, thermal data, radar data, spectral library development, and inter-software programming.

(a) *Hyperspectral Data.* Hyperspectral image processing techniques manage narrow, continuous bands of spectral data. Many hyperspectral systems maintain over 200 bands of spectral data. The narrow bands, also known as channels, provide a high level of detail and resolution. This high resolution facilitates the identification of specific objects, thereby improving classification (Figure 5-24). The advantage of hyperspectral imaging lies in its ability to distinguish individual objects that would be otherwise grouped in broadband multi-spectra imagery. Narrow bands are particularly useful for mapping resources such as crop and mineral types. The narrow, nearly continuous bands create large data sets, which require advance software and hardware to store and manipulate the data.

Figure 5-25. Hyperspectral classification image of the Kissimmee River in Florida (Image created by Lowe Engineers - LLC and SAIC, 2003). Classifications of 28 vegetation communities are based on a supervised classification.

(b) *Thermal Data.* Thermal image processing techniques are used to image objects by the analysis of their emitted energy (Figure 5-26). The thermal band wavelength ranges are primarily 8 to 14 μm and 3 to 5 μm . The analysis of thermal data is typically used in projects that evaluate surface temperatures, such as oceans and ice sheets, volcano studies, and the emission of heat from man-made objects (e.g., pipelines).

Figure 5-26. Close-up of the Atlantic Gulf Stream. Ocean temperature and current mapping was performed with AVHRR thermal data. The temperatures have been classified and color-coded. Yellow = water 23°C (73°F), green = 14°C (57°F), blue = 5°C (41°F). Taken from <http://www.osdpd.noaa.gov/PSB/EPS/EPS.html>.

(c) *Radar.* Radar (radio detection and ranging) systems are able to penetrate cloud cover in certain wavelengths. This technology is useful for imaging day or night surface features during periods of intense cloud cover, such as storms, smoke from fire, or sand and dust storms (Figure 5-27).

Figure 5-27. Radarsat image, pixel resolution equals 10 m. Image is centered over the Illinois River (upper left), Mississippi River (large channel in center), and the Missouri River (smaller channel in center. Chapter 6 case study 3 details the analysis of this scene. Taken from Tracy (2003).

g. Customized Spectral Library. Many software programs allow users to build and maintain a customized spectral library. This is done by importing spectra signatures from objects of interest and can be applied to identify unknown objects in an image.

h. Internal Programming.

(1) Image processing software allows users to develop computing techniques and unique image displays by programming from within the software package. Programming gives the user flexibility in image manipulation and information extraction. The users' manual and online help menus are the best resources for information on how to program within particular software.

(2) New applications in image processing and analysis are rapidly being developed and incorporated into the field of remote sensing. Other advanced uses in image processing include the modification of standard methods to meet individual project needs and improving calibration methods. Go to http://www.techexpo.com/WWW/opto-knowledge/IS_resources.html for more

information on advanced and specialized hardware and software and their applications.

i. *The Interpretation of Remotely Sensed Data.* There are four basic steps in processing a digital image: data acquisition, pre-processing, image display and enhancement, and information extraction. The first three steps have been introduced in this and previous chapters. This section focuses on information extraction and the techniques used by researchers to implement and successfully complete a remote sensing analysis. The successful completion of an analysis first begins with an assessment of the project needs. This initial assessment is critical and is discussed below.

(1) *Assessing Project Needs.* Initiating a remote sensing project will require a thorough understanding of the project goals and the limitations accompanying its resources. Projects should begin with an overview of the objectives, followed by plans for image processing and field data collection that best match the objectives.

(a) An understanding of the customer resources and needs will make all aspects of the project more efficient. Practicing good client communication throughout the project will be mutually beneficial. The customer may need to be educated on the subject of remote sensing to better understand how the analysis will meet their goals and to recognize how they can contribute to the project. This can prevent false expectations of the remotely sensed imagery while laying down the basis for decisions concerning contributions and responsibilities. Plan to discuss image processing, field data collection, assessment, and data delivery and support.

(b) The customer may already have the knowledge and resources needed for the project. Find out which organizations may be in partnership with the customer. Are there resources necessary for the project that can be provided by either? It is important to isolate the customer's ultimate objective and learn what his or her intermediate objectives may be. When assessing the objectives, keep in mind the image classification needed by the customer and the level of error they are willing to accept. Consider the following during the initial stages of a project:

- What are the objectives?
- Who is the customer and associated partners?
- Who are the end users?
- What is the final product?
- What classification system is needed?
- What are the resolution requirements?
- What is the source of image data?
- Does archive imagery exist?
- Is season important?
- What image processing software will be used? Is it adequate?
- What type of computer hardware is available? Is it adequate?
- Is there sufficient memory storage capacity for the new imagery?

- Are hardware and software upgrades needed? Who will finance upgrades?
- Are plotters/printers available for making hardcopy maps?
- Can the GIS import and process output map products?

(c) Field considerations:

- What are the ecosystem dynamics? What type of field data will be required?
- Will the field data be collected before, after, or during image acquisition?
- Who will be collecting the field data?
- What sampling methods will be employed?
- What field data analysis techniques will be required?
- Who will be responsible for GPS/survey control?
- Who will pay for the field data collection?
- Is the customer willing to help by providing new field data, existing field data, or local expertise?

(2) *Visualization Interpretation.*

(a) Remotely sensed images are interpreted by visual and statistical analyses. The goal in visualization is to identify image elements by recognizing the relationship between pixels and groups of pixels and placing them in a meaningful context within their surroundings. Few computer programs are able to mimic the adroit human skill of visual interpretation. The extraction of visual information by a human analyst relies on image elements such as pixel tone and color, as well as association. These elements (discussed in Chapter 2) are best performed by the analyst; however, computer programs are being developed to accomplish these tasks.

(b) Humans are proficient at using ancillary data and personal knowledge in the interpretation of image data. A scientist is capable of examining images in a variety of views (gray scale, color composites, multiple images, and various enhancements) and in different scales (image magnification and reduction). This evaluation can be coupled with additional information such as maps, photos, and personal experience. The researcher can then judge the nature and importance of an object in the context of his or her own knowledge or can look to interdisciplinary fields to evaluate a phenomena or scene.

(3) *Information Extraction.* Images from one area of the United States will appear vastly different from other regions owing to variations in geology and biomes across the continent. The correct identification of objects and groups of objects in a scene comes easily with experience. Below is a brief review of the spectral characteristics of objects that commonly appear in images.

(a) *Vegetation.* Vegetation is distinguished from inorganic objects by its absorption of the red and blue portions of the visible spectrum. It has high reflectance in the green range and strong reflectance in the near infrared. Slight variability in the reflectance is ascribable to differences in vegetation morphology,

such as leaf shape, overall plant structure, and moisture content. The spacing or vegetation density and the type of soil adjacent to the plant will also create variations in the radiance and will lead to “pixel mixing.” Vegetation density is well defined by the near infrared wavelengths. Mid-infrared (1.5 to 1.75 μm) can be used as an indication of turgidity (amount of water) in plants, while plant stress can be determined by an analysis using thermal radiation. Field observations (ground truth) and multi-temporal analysis will help in the interpretation of plant characteristics and distributions for forest, grassland, and agricultural fields. See Figures 5-28 and 5-29.

Figure 5-28. Forest fire assessment using Landsat imagery (Denver, Colorado). Image on the left, courtesy of NASA, was collected in 1990; image on the right was collected in 2002 (taken from <http://landsat7.usgs.gov/gallery/detail/178/>). Healthy vegetation such as forests, lawns, and agricultural areas are depicted in shades of green. Burn scars in the 2002 image appear scarlet. Together these images can assist forest managers in evaluating extent and nature of the burned areas.

(b) *Exposed Rock (Bedrock).* Ground material such as bedrock, regolith (unconsolidated rock material), and soil can be distinguished from one another and distinguished from other objects in the scene. Exposed rock, particularly hydrothermally altered rock, has a strong reflectance in the mid-infrared region spanning 2.08 to 2.35 μm . The red portion of the visible spectrum helps delineate geological boundaries, while the near infrared defines the land–water boundaries. Thermal infrared wavelengths are useful in hydrothermal studies. As discussed in earlier sections, band ratios such as band 7/band 5, band 5/band 3, and band 3/band 1 will highlight hydrous minerals, clay minerals, and minerals rich in ferrous iron respectively. See Figure 5-30.

(c) *Soil.* Soil is composed of loose, unconsolidated rock material combined with organic debris and living organisms, such as fungi, bacteria, plants, etc. Like exposed rock, the soil boundary is distinguished by high reflectance in

the red range of the spectrum. Near infrared wavelengths highlight differences between soil and crops. The thermal infrared region is helpful in determining moisture content in soil. See Figure 5-31.

Figure 5-29. Landsat scene bands 5, 4, 2 (RGB). This composite highlights healthy vegetation, which is indicated in the scene with bright red pixels. Taken from <http://imagers.gsfc.nasa.gov/ems/infrared.html>.

Figure 5-30. ASTER (SWIR) image of a copper mine site in Nevada. Red/pink = kaolinite, green = limestones, and blue-gray = unaltered volcanics. Courtesy of NASA/GSFC/METI/ERSDAC/JAROS, and U.S./Japan ASTER Science Team.

(d) *Water (Water, Clouds, Snow, and Ice)*. As previously mentioned, the near infrared defines the land–water boundaries. The transmittance of radiation by clear water peaks in the blue region of the spectrum. A ratio of band 5/band 2 is useful in delineating water from land pixels. Mid-infrared wavelengths in the 1.5- to 1.75-mm range distinguishes clouds, ice, and snow. See Figure 5-32.

(e) *Urban Settings*. Objects in an urban setting include man-made features, such as buildings, roads, and parks. The variations in the materials and size of the structure will greatly affect the spectral data in an urban scene. These features are well depicted in the visible range of the spectrum. Near infrared is also useful in distinguishing urban park areas. Urban development is well defined in false-color and true color aerial photographs, and in high resolution hyperspectral data. The thermal infrared range (10.5 to 11.5 μm) is another useful range owing to the high emittance of energy. A principal components analysis may aid in highlighting particular urban features. See Figure 5-33.

Figure 5-31. AVIRIS image, centered on Arches National Park, produced for the mapping of cryptogamic soil coverage in an arid environment. Taken from <http://speclab.cr.usgs.gov/PAPERS.arches.crypto.94/arches.crypto.dri.html>.

Figure 5-32. MODIS image of a plankton bloom in the Gulf of St. Lawrence near Newfoundland, Canada. Ground pixel size is 1 km. In this image, water and clouds are easily distinguishable from land (green pixels at top left of scene). Taken from <http://rapidfire.sci.gsfc.nasa.gov/gallery/?2003225-0813/Newfoundland.A2003225.1440.1km.jpg>.

Figure 5-33. Orlando, Florida, imaged in 2000 by Landsat 7 ETM+ bands 4, 3, 2 (RGB). The small circular water bodies in this image denote the location of karst features. Karst topography presents a challenge to development in the Orlando area. Taken from <http://edcwww.cr.usgs.gov/earthshots/slow/Orlando/Orlando>

(f) *Other Landscape Features.* A variety of unique landscape features are easily imaged with remote sensing. A few examples are illustrated below: Volcanic eruption (Figure 5-34), forest fires (Figure 5-35), abandoned ships (Figure 5-36), dust storm (Figure 5-37), oil fires (Figure 5-38), and flooding (Figure 5-39).

Figure 5-34. Landsat image of Mt. Etna eruption of July 2001. Bands 7, 5, 2 (RGB) reveal the lava flow (orange) and eruptive cloud (purple). Taken from <http://www.usgs.gov/volcanoes/etna/>.

Figure 5-39. The mosaic of three Landsat images displays flooding along the Mississippi River, March 1997.

j. Statistical Analysis and Accuracy Assessment. Accuracy assessment means the correctness or reliability in the data. Error is inherent in all remote sensing data. It is important to establish an acceptable level of error and to work within the resolution of the image. Working within the means of the resolution of an image is important for maintaining the desired accuracy. Attempting to extract information from an image for which objects are not clearly resolvable will likely lead to incorrect assumptions. Error can be introduced during acquisition by the sensor and while performing geometric and radiometric correction and image enhancement processes. Another major source of error lies in the misidentification and misinterpretation of pixels and groups of pixels and their classification.

(1) *Resolution and RMS (Root Mean Squared)*. Some errors are simple to quantify. For instance, the image pixel in a TM image represents the average radiance from a 30- × 30-m area on the ground. So, measurements within a TM scene will only be accurate to within 30 m. Positional accuracy may be established by a comparison with a standard datum giving an absolute uncertainty value. The RMS (root mean squared) error is automatically calculated during image rectification. This error can be improved while designating GCPs (Ground Control Points; see Paragraph 5-17).

(2) *Overall Accuracy*. Overall accuracy can be established with “Ground truth.” Ground truth is site-specific and measures the accuracy by sampling a number of areas throughout a scene. Overall accuracy of an image is then calculated by modeling the difference between the observed pixel DN signature and known object on the ground.

(3) *Error Matrices*. Assessing classification error is more involved. Solving for this type of error requires a numerical statistical analysis. Some software incorporates accuracy assessment within the classification function. For instance, classification error assessment compares an image classification matrix with a reference matrix. See Paragraph 5-20d(4) for information on classification accuracy. In this type of assessment, the reference data are assumed correct. Pixels are assessed in terms of their mistaken inclusion or exclusion from an object class; this is known as commission and omission (see Congalton and Green, 1999). All known error should be noted and included in any assessment. Review Congalton and Green (1999) for further information on the practice of error assessment.

k. Presenting the Data. Once a visual and statistical evaluation has been performed, the analysis must be presented in a manner that best communicates the information needed. The information may be presented as a hardcopy printout of the image or presented as a map (Figure 5-40). The information may also be displayed as a statistical database, which includes data tables and graphs. Knowledge of GIS, cartography, and spatial analysis is helpful in choosing and executing the manner in which the data will be presented. For instance, a number of GIS software programs are capable of displaying the image in a map format with a linked data set. Be sure to keep in mind the final product needed by the client.

Figure 5-40. The final product may be displayed as a digital image or as a high quality hard copy. Taken from Campbell (2003).

Chapter 6.

Remote Sensing Applications in USACE

6-1 Introduction. Remote Sensing is currently used by Corps scientists and engineers at the seven research and development laboratories as well as at the Districts and Divisions. Remote sensing has proven to be a cost effective means of spatially analyzing the environment and is particularly useful in regions with limited field access. A vast amount of literature covering remote sensing applications in environmental and engineering projects has been published and much of it is available through the ERDC and USACE library system. This chapter only touches the surface of the material that describes the variety of applications and products in use. Some of the references listed in Appendix A also have internet web sites providing more in-depth information on the subject of remote sensing and current research.

6-2 Case Studies.

a. Each study presented below uses remote sensing tools and data. Special emphasis have been placed on Corps works and contracted work related to civil projects. Non-Corps projects, such as NASA works, are also presented in an effort to provide broader examples of the potential use of remote sensing and to aid in the implementation of remote sensing into existing and future US Army Corps of Engineers projects. This chapter 1) reviews the capabilities of sensors, 2) illustrates the value of remote sensing data analysis and integration into spatial data management systems, and 3) communicates recent studies to promote cooperation between Corps Districts, local government, and the general public.

b. The following topics are presented in this chapter:

- Water Quality.
- Wetland mitigation.
- Archeology.
- Engineering.
- Soil science—sediment transport.
- Forestry.
- Agriculture.
- Environmental projects.
- DEM generation.
- Applications in snow and ice.
- Emergency Management.

6-3 Case Study 1: Kissimmee River Restoration Remote Sensing Pilot Study Project Final Report

- *Subject Area:* Environmental Assessment.
- *Purpose:* To evaluate the vegetative response to the restoration of the Kissimmee River floodplain ecosystem using hyperspectral data.
- *Data Set:* Hyperspectral Airborne.

a. Introduction. Historically, the Kissimmee River meandered 103 miles (~166 km), connecting Lake Kissimmee to Lake Okeechobee. The river and its floodplain supported diverse wetland communities including aquatic and terrestrial plants and animals. The Kissimmee River was hydrologically unique owing to prolonged and extensive flood inundation. During the 1960s, the river and its 1- to 2-mile (1.6- to 3.2-km) wide floodplain was channelized and drained in an effort to control flooding. Canal excavation eliminated one-third of the channel, and drainage destroyed two-thirds the floodplain. This Corps of Engineers project led to a significant decrease in waterfowl, wading bird, and fish populations.

(1) An environmental restoration plan is underway in an attempt to restore the pre-1960 ecosystem in the Kissimmee River floodplain. The USACE Jacksonville District and the South Florida Water Management District are jointly responsible for this 3000- square mile (7770 km²) restoration project. The primary goal of the restoration project is to re-establish a significant portion of the natural hydrologic connectivity between Lake Kissimmee and Lake Okeechobee. With the natural hydrologic conditions in place, the objective of the project is to rebuild the wetland plant communities and restore the local biological diversity and functionality.

(2) The study reviewed here represents a pilot study conducted by SAIC (Science Applications International Corporation) to establish a baseline for environmental monitoring of the Kissimmee Restoration Project. Their study explored the utility of hyperspectral image data in aiding vegetative mapping and classification. The hyperspectral remote sensing data demonstrated themselves to be highly useful in delineating complex plant communities. Continued use of such a data set will easily aid in the management of the Kissimmee River Restoration Project.

b. Description of Methods. The test area within the restoration site was chosen by USACE. Preliminary field studies conducted in 1996, established approximately 70 plant communities, a handful of which were not present during the study of interest (conducted in 2002). It was determined that the rapid changes in hydrologic conditions had altered the plant community structure during the interim between studies; in places, some plant species and groups had entirely disappeared. Researchers monitoring the vegetation restoration at the Kissimmee site were concerned with the establishment of native versus non-native invasive and exotic plant species. The colonization by non-native plant species, such as Brazilian Pepper and Old World Climbing Fern, are of interest because of their potential affect on other revitalization efforts; those focusing on fauna restoration, for instance. The spectral analysis of heterogeneous plant species communities is difficult owing to the commonality of plant chemistry and morphology. The spectral difference between native and non-native plants is therefore narrow, and difficulties in distinguishing them are compounded by their mixing (or sharing of habitat). Additionally, the domination by one plant species in many places added to the problem of accurately classifying the plant communities. See below for vegetation classes established for this study.

(1) Examples of vegetation classes include:

- Aquatic vegetation.

- Broadleaf marsh.
- Miscellaneous wetland vegetation.
- Upland forest.
- Upland herbaceous.
- Upland shrub.
- Wetland forest.
- Wetland shrub.
- Wet prairie.
- Vines

(2) Geological constraints did not aid in the identification of the vegetation classes. Geologic constraints tend to be more useful in mapping plant communities in areas with a more mature ecosystem or where there is significant variation in the substrate or soil. Choosing a sensor capable of delineating healthy vegetation versus stressed vegetation was another consideration that needed to be addressed by the researchers. This would allow land use managers the opportunity to closely monitor the decline and rise of various species throughout the duration of the wetland restoration.

c. Field Work.

(1) Airborne hyperspectral data were collected in conjunction with 146 ground-truth data points (also known as training sites); this collection was made on-foot and by airboat. Fieldwork was done and data collected during a flood by a botanist and a GIS specialist. In the field, SAIC's hand held spectrometer was used to collect the spectral data associated with mixed plant communities from within the Kissimmee River floodplain. These ground-control points were then used to test the accuracy of the vegetation map developed from the hyperspectral data.

(2) Problems arose using the plant classes defined by the 1996 field study. Classes were subsequently altered to better suit the dechannelized ecology. A supervised classification was applied to the data and two vegetation maps were produced denoting 68 vegetation communities and 12 plant habitat types (Figure 5-25). The hyperspectral map was then compared to the existing vegetation map produced in 1996.

d. Hyperspectral Sensor Selection. Researchers on this project had the opportunity to choose between AVIRIS and HyMap. HyMap was eventually chosen for its accuracy, spectral capabilities, and reasonable expense. HyMap, a hyperspectral sensor (HSI), was placed on board a HyVista aircraft. HyMap maintains 126 bands across the 15- to 20-nm range. The error in HyMap data was found to be at ± 3 m, equivalent to the accuracy of the on board GPS unit. To learn more about HyMap and HyVista view <http://www.hyvista.com/main.html>.

(1) For this project, the hyperspectral (HSI) data maintained clear advantages over other sensor data. HSI's high spectral resolution allows for the distinction of spectrally similar vegetation and had the potential to monitor vegetation health status. The shortwave infrared (SWIR) wavelengths were found to be most sensitive to the non-photosynthetic

properties in the vegetation. This further helped to discriminate among the vegetation classes.

(2) HyVista pre-processed the digital data. Pre-processing included a smoothing algorithm to reduce the signal to noise ratio (SNR) across the scene, to an impressive >500:1. The data were geographically rectified using ground control points identified on a geo-registered USGS orthophoto. The geo-positional accuracy was determined to be within ± 3 pixels across 95% of the scene. This was established by comparing the image with a high-resolution orthophoto. A digital orthophoto was then overlaid on top of the digital hyper-spectral data to verify geo-positional accuracy.

e. Study Results. Analyst used KHAT (Congalton, 1991), a classification statistic used to test the results of supervised versus unsupervised classification (Equation 6-1). KHAT considers both omission and commission errors. Statistically it is “a measure of the difference between the actual agreement between reference data and the results of classification, and the chance agreement between the reference data and a random classifier” (see <http://www.geog.buffalo.edu/~lbian/rsoc17.html> to learn more on accuracy assessment). KHAT values usually range from 0 to 1. Zero indicates the classification is not better than a random assignment of pixels; one indicates that the classification maintains a 100% improvement from a random assignment. KHAT values equaled 0.69 in this study, well within the 0.6 to 0.8 range that describes the class designation to be “very good” (≥ 0.8 is “excellent”). For this study, KHAT indicated good vegetative mapping results with the supervised classification for distinguishing plant species and for mapping surface water vegetation. The KHAT also verified the potential value of image classification to map submerged aquatic vegetation using HIS data.

$$k = \frac{\text{observed accuracy} - \text{chance agreement}}{1 - \text{chance agreement}} \quad (6-1)$$

$$N \sum_{i=1}^r x_{ii} - \sum_{i=1}^r (x_{i+} \times x_{+i})$$

$$k = N2 - \sum_{i=1}^r (x_{i+} \times x_{+i})$$

where

- r = number of rows in the error matrix
- x_{ii} = number of observations in row i and column i (the diagonal)
- x_{i+} = total observations of row i
- x_{+i} = total observations of column i
- N = total of observations in the matrix .

The estimated time savings of the mapping project as compared with the manual analysis using color infrared was calculated to be a factor of 10 or better. Additional benefits include a digital baseline for change detection and managing restoration. The study did not establish under which conditions HSI did not work. HSI processing and analyses was shown to be a generally valuable tool in a large-scale riparian restoration.

f. Conclusions. HSI's advantages over aerial panchromatic and color infrared include its ability to automate data processing rapidly; this will be highly useful for change detection if the hyperspectral data are collected over time. This data can then be easily coupled with other useful GIS data when researchers attempt to combine hydrographic and wildlife data. Wetland hyperspectral imaging paired with advanced data processing and analysis capabilities were shown to be a valuable tool in supporting large-scale programs, such as the Comprehensive Everglades Restoration Program (CERP). For continued successful management of the Kissimmee Restoration Project, the Corps' Jacksonville District and the South Florida Water Management District will have to decide on a mapping method that provides the detail needed to monitor plant community evolution while balancing this need with budget constraints.

Point of Contact: Wiener Cadet, Project Manager, Phone: (904) 232-1716

6-4 Case Study 2: Evaluation of New Sensors for Emergency Management

- *Subject Area:* Emergency Management.
- *Purpose:* To test the resolvability of high-resolution imaging to evaluate roof condition.
- *Data Set:* Visible and infrared.

a. Introduction.

(1) Emergency response and management efforts are best facilitated with timely and accurate information. Typically, these data include an enormous amount of geo-spatial information detailing the extent and condition of damage, access to emergency areas or support services, and condition of urban infrastructure. Remotely sensed imagery has the capability of delivering this type of information, but it is best combined with geo-spatial data when they are rectified and pre-processed in a way that allows for easy visual and algorithm analysis. The amalgamation of geo-spatial data into one comprehensive map will aid emergency management organizations in their effort to coordinate and streamline their response.

(2) Understanding the utility and limitations of a sensor is highly valuable to emergency response workers. This study evaluated the effectiveness of Emerge, a new airborne sensor that collects visible and infrared radiation. Emerge was tested in relation to four primary requirements, listed below.

- Ground sampling distance (GSD).
- Capability for storing large volumes of digital data.
- Pre-processing and the vendors ability to orthorectify up to "500 single frames of imagery in 12 hours or less" and save these data onto a CD-ROM or ftp for fast delivery.
- Indexing system for all resolutions collected, allowing for easy determination of image location.

b. Description of Methods. Originally, this study intended to evaluate roof damage caused by an actual emergency. In the absence of such an emergency, alternate imagery was collected over a housing development under construction in Lakeland, Florida, located 30 miles (48 km) northeast of Tampa, Florida. The different phases of housing construction provided an analog to roof damage during an event such as strong winds or a hurricane. The different structural states of both residential and commercial roofs included exposed rafters, exposed plywood, and plywood covered by tarpaper or shingles.

c. Field Work. Initially, field reconnaissance established the appropriateness of using two neighboring test areas in Lakeland, Florida. Roof conditions at individual buildings were evaluated and geo-referenced. After the first flight, an assessment of the ground sampling distance (GSD) and sensor data determined that a finer resolution would be required to adequately examine roof condition. Two additional flights were then acquired, resulting in a collection of data gathered at resolutions of 3, 2, and 1 ft (91.4-, 61-, and 30.5- cm respectively), and 8-in (20.3 cm). Landscaping features, such as tree type and leaf on/off state, were also documented with digital photos. This information was later used to establish the feasibility in mapping vegetation using the Emerge system.

d. Sensor Data Acquisition. The two test sites, occupying 8 square miles ($\sim 21 \text{ km}^2$), were surveyed at several resolutions using Emerge imagery (see http://www.directionsmag.com/pressreleases.php?press_id=6936 for more details on the Emerge System). Multiple resolutions were collected over a 2-month period. As a result, a one-to-one comparison of the effect of resolution on image analysis was difficult, as house construction in some areas was completed during the 2-month interval. The volume of data collected was equivalent to that required for a 60 square mile ($\sim 155 \text{ km}^2$) area, with approximately 25% image overlap (at a single resolution). This volume of data totaled 5 gigabits.

e. Study Results. Evaluation of the imagery showed that roof rafters were best resolved at a 1-ft and 8-in. (30.5 and 20.3 cm) resolution. At this resolution, plywood can be distinguished from other construction materials and individual rafters can be observed. Tarpaper was not distinguishable from shingles owing to their spectral similarities.

(1) Despite the functionality of the 1-ft and 8-in (30.5 and 20.3 cm) resolutions, in places with bright spectral response, saturation on the high end of the intensity scale lowered the resolvability of rafters relative to the flooring material. This was the result of a high gain set for radiation detection within the sensor. Over-saturation lowers the contrast between rafters and the flooring, making it difficult to fully evaluate the condition of the roof. Lowering radiation saturation requires collecting data during low to medium sun angle. This may, however, delay data acquisition.

(2) Sun angle controls image contrast in two ways. First, a low sun angle may increase shadowing, leading to a loss in target radiation data. Secondly, a high sun angle may over-saturate the sensor. Both extremes were shown to lower contrast in this study, making roof analysis difficult.

(3) A scatter plot breakdown of band 1 relative to band 2 was performed to evaluate the possibility of automating an analysis that would delineate intact roofs and damaged

roofs. A preliminary analysis suggests that this is possible because of the strong covariance displayed by roofs shingled with monochromatic materials. Any automated process developed would need to address the limitations posed by non-monochromatic shingles (which would appear spectrally mixed and indistinguishable from damaged roofs).

(4) A vegetation analysis was also explored to test the resolution required to accurately describe tree type and condition. At the 1-ft (30.5 cm) resolution, researchers were able to determine leaf on/off conditions (data were collected in February). However, at this resolution it was not possible to delineate any details regarding leaf morphology. At the 8-in (20.3 cm). resolution, palms were distinguishable, although it was not possible to differentiate broad versus narrow leaves.

f. Conclusions. Evaluation of the Emerge sensor led to the development of a detection matrix. This matrix reviews the capabilities of the sensor at various spatial resolutions for all objects studied (see Table 6-1). This study determined that Emerge could adequately meet the requirements of emergency management systems. High-resolution data can be acquired within 4 hours of the plane's landing. This includes the time needed for pre-processing (orthorectification and the production of geo-TIFF files for CD-ROM and ftp). Shingles and tarpaper are not resolvable, though rafters and plywood are at the 2-ft (~61 cm) resolution. For high-resolution images, a medium sun angle increased roof detail. Palm trees and leaf on/off conditions can be visually identified at the 8-in (20.3 cm). resolution; however, broad-leafed trees cannot be distinguished from narrow-leafed trees. The only limitations placed on these data centered on over-saturation and sensor inability to distinguish tree types. The covariance displayed by band 1 relative to band 2 indicates the potential success for developing an automated algorithm to locate and count damaged roofs.

Table 6-1
Detection Matrix for Objects at Various GSDS

Objects/GSD	3-ft (91.4)	2-ft (61 cm)	1-ft (30.5 cm)	8-in. (20.3 cm)
Roof rafters	Not visible	Barely visible	Often visible	Visible
Shingles/tarpaper (other) vs. plywood	Can sometimes separate	Can often separate	Can determine wood vs. other cover	Can determine wood vs. other cover
Rafters in 3-band saturation	Causes rafter detail loss	Causes rafter detail loss	Causes rafter detail loss	Causes rafter detail loss
Broad-leaf vs. narrow-leaf	Cannot separate	Can determine leaf on/off	Can determine leaf on/off	Palms are always visible
All in cloud shadow	Degrades image	Some info recoverable	Some info recoverable	Some info recoverable
Roofs as a function of sun zenith angle	Best detail, near zero angle, overhead sun	Best detail, medium angle, shadow casting	Best detail, medium angle, shadow casting	Best detail, medium angle, shadow casting
All in 1, 2, 3 RGB, 2 Σ stretch	Enhances imagery	Enhances imagery	Enhances imagery	Enhances imagery

6-5 Case Study 3: River Ice Delineation with RADARSAT SAR

- *Subject Area:* Ice monitoring
- *Purpose:* To evaluate the concentration and condition of river ice.
- *Data Set:* RADARSAT SAR

a. Introduction. Remote sensors operating in the microwave region of the spectrum have the advantage of seeing through clouds and atmospheric haze. RADARSAT SAR (synthetic aperture radar) collects spectral data in the microwave region and is capable of imaging ground targets during adverse weather conditions, such as storms. Additionally, RADARSAT SAR collects 10-m pixel sized data, a high spatial resolution well suited for studies examining ice in narrow river channels. The study reviewed here explored RADARSAT SAR's potential in delineating and monitoring ice and ice floes in rivers ranging in stream widths of 160 to 1500 m. A better estimate of ice conditions along large streams will allow for better navigation planning and will provide river dam regulators the information needed to plan and prepare for ice breakup and floes.

b. Description of Methods. Three rivers of varying widths were evaluated for ice cover over the course of two winters (2002 and 2003). The first winter was relatively mild with partial river ice development at the three sites. Winter 2003 possessed a number of below freezing days and was an ideal time for examining river ice in the northern mid-west. The rivers chosen for this study were the Mississippi River near St. Louis, Missouri, the Missouri River at Bismarck, North Dakota, and the Red Lake River in Grand Forks, North Dakota. Each site offered unique contributions to the study. The Mississippi River represented a stream with heavy navigation use, the Missouri River site included a hydropower dam, while the Red Lake River had extensive ice jam and flood records. Coordinated efforts among CRREL researchers, the local Corps Districts, and the RADARSAT International (RSI) aided in the acquisition and timing of satellite data collection.

(1) Stream channels were subset and isolated for river ice classification. To accomplish this, a band ratio was applied to Landsat TM data. They were then classified by an unsupervised process and extracted for mask overlay onto the radar data. This sufficiently outlined the land/water boundaries and isolated the stream in images with wide river channels. This process omitted vegetation and islands from the resultant image. The subsequent SAR subset did not include mixed pixels (land/water/ice).

(2) Images with narrow channels required hand-digitization and a textural analysis, followed by a supervised classification (to further eliminate land pixels). The hand-digitization proved less successful than the Landsat TM overlay and extraction method. Hand-digitization did not thoroughly omit pixels with mixed water, vegetation, and land (i.e., river islands).

(3) In the SAR images, only the channel reaches were analyzed for ice conditions using an unsupervised classification. The classification mapped brash ice (accumulated floating ice fragments), river channel sheet ice, shore ice, and open water.

c. Field Work. Direct field observations were not necessary as a web-camera mounted on a bridge provided the visual documentation of ice conditions in the river. At the Missouri River site, web-cameras have been strategically placed in a variety of locations in the US by ERDC/CRREL. To view the Missouri River images used in this study, as well as other river web-camera images, go to <http://webcam.crrel.usace.army.mil>. Study sites without a web-camera relied on District contacts for field information. At Red Lake River near Grand Forks, North Dakota, field reconnaissance ice surveys were conducted by the Corps St. Paul, Minnesota, District office.

d. Sensor Selection and Image Post-Processing.

(1) As stated above, RADARSAT SAR data was chosen for this study. Radar data have already proven their utility in sea ice mapping and monitoring (Carsey, 1989). Radar can aid in determining ice concentration, classification, ice motion monitoring, and ice feature changes. The study reviewed here adapted methods used to study large ice sheets to the evaluation of smaller more temporal river ice.

(2) The acquired radar images were visually analyzed and classified using an unsupervised classification to delineate open water, moving ice floes, and stationary ice covers. The delineation of river channels was undertaken by two methods, described above (hand-digitization and TM extraction and overlay).

e. Study Results. The following description summarizes the ice condition results stemming from each river surveyed:

“In the Mississippi River imagery near St. Louis, Missouri, the wide channel width (500–2000 meters) contributed to identifying river ice with RADARSAT imagery. In the 2002 image it was determined that 30% of the channel had ice in the flow, and in the 2003 image, it was determined that there was 100% ice cover. Additionally, this ice cover was separated into forms of ice; brash ice and border ice. In the 2003 image it is believed that the brash ice formed as a result of navigation ice-breaking activities.

(1) In the Missouri River imagery near Bismarck, North Dakota, the channel width (400–1000 m) was suitable, and river ice was determined from the RADARSAT imagery. The 2002 image showed that 77% of the channel had ice in the flow, and in the 2003 image, only 21% of the channel had ice. The 2003 imagery was acquired before full icing conditions, and a small amount of ice was interpreted to exist.

(2) In the Red Lake River imagery near the confluence with the Red River of the North at Grand Forks, North Dakota, the river channel is narrow (40–75 m). The narrowness of the channel limited the process of delineating the channel boundary on the imagery. As a result of the narrow channel width, river ice was not determined by this process. However, ice surveys were conducted by the US Army Corps of Engineers during the time of image acquisitions, and an ice cover was recorded in both 2002 and 2003.

f. Conclusions. RADARSAT SAR data were able to detect ice on rivers with widths ranging from 400 to 2000 m. Despite RADARSAT’s 10-m resolution, this data set was unable to detect the presence of ice on the narrower Red Lake River, with a width of 40–75 m. RADARSAT’s overall suitability for detecting river ice and ice conditions was shown to be

of potential use. The method presented here details an important tool that may aid in hazardous wintertime navigation and assist dam regulators on decisions regarding stream flow and reservoir levels.

6-6 Case Study 4: Tree Canopy Characterization for EO-1 Reflective and Thermal Infrared Validation Studies in Rochester, New York

- *Subject Area:* Forestry and climate change
- *Purpose:* To collect forest canopy structure and temperature data.
- *Data Set:* Multispectral and hyperspectral

a. Introduction. Tree and forest structure respond strongly to environmental conditions and change. Subsequently, studies have successfully shown the utility of remote sensing in monitoring environmental conditions through the analysis of vegetation. The study reviewed here surveyed a mixed forest in northern New York State in an attempt to better understand the interaction between solar radiation and tree/forest structure. An additional objective of this study was to validate the Earth Observing satellite (EO-1, launched in 2000). The validation was performed by comparing the EO-1 satellite data with that of the Landsat-7 ETM+ data. The EO-1 satellite acquired data at the same orbit altitude as Landsat-7 while flying approximately 1 minute behind. EO-1 reflective bands were combined with the Landsat-7 ETM+ thermal infrared bands to estimate canopy temperature. The 1-minute delay in synchronization between the two sensors was evaluated to test the effects of separating the thermal and reflective measurements in time. Relating scene exitance (the radiative flux leaving a point on a surface, moving in all directions) and reflectance to the landscape provided insight to prevailing environmental characteristics for the region.

b. Description of Methods. Ground and tree canopy data were collected from mature healthy forest stands at a site in Durant-Eastman Park in Rochester, New York. Characterization of the forest included a stem and trunk survey, tree structure geometry measurements, regional meteorology, and leaf area index (LAI) measurements (see <http://www.uni-giessen.de/~gh1461/plapada/lai/lai.html> for more information on LAI). Two smaller field sites, Ballard Ridge and Smith Grove, were selected for detailed study from within the larger forested area. Tree heights for both sites averaged 20–30 m. Ballard Ridge consisted of a dense mature stand of maple, cottonwood, elm, and oak trees. The Smith Grove consisted of a dense mature stand of locust trees and cottonwood. Thermal and reflective spectral measurements were made on leaves, tree bark, leaf litter, soil, and grass.

c. Field Work. Leaf area index (LAI) was calculated in the field with the use of a non-imaging instrument, which measures vegetation radiation in the spectrum of 320–490 nm. Leaf area index is a ratio of the foliage area in a forest canopy relative to the ground surface area. It estimates the photosynthetic capability of a forest. The measured light intensity was used to calculate the average LAI for each location within the field site. High-resolution hemispherical photographs were collected at each site using a digital camera with a fisheye lens (148° field-of-view). The digital photographs were taken during the early morning and

late evening hours to reduce the effects of atmospheric haze. The digital hemispherical photographs were later analyzed using a specialized forestry software, which measures both LAI and canopy leaf structure. LAI calculations based on the computed hemispherical digital images compared favorably with the LAI measurements from the meter instrument.

d. Sensor System.

(1) Satellite data were collected with the use of Landsat MTI, Hyperion, and ALI (Advanced Land Imager) on 25 August 2001. The ALI sensor has nine spectral bandwidths plus a panchromatic band. Three bands were analyzed for this study 773.31 nm, 651.28 nm, and 508.91 nm. The forested areas appear bright red, urban areas are gray-blue, and the water is depicted by the dark blue regions.

(2) The sensor radiance was converted with the use of 6S, an atmospheric corrections model that converts sensor radiance to estimated surface reflectance. The differences and consistencies in the two sensors were then easily compared with the spectral data collected in the field. Then, a more detailed study of the forest site was made, using measured geometric and optical parameters as input to the SAIL multi-layer canopy reflectance model. The ETM+ and ALI data were then compared with the SAIL (Scattering by Arbitrarily Inclined Leaf) reflectance model and the high resolution Hyperion, a hyperspectral imaging instrument (see <http://eo1.usgs.gov/instru/hyperion.asp> for details).

e. Study Results. A comparison of the panchromatic ETM+ and ALI data show dramatic differences. The ALI data provided better definition of the marina and pier area as well as natural water features (urban and water targets). Relative to the ETM+ images the ALI data maintained a reduced DN value for all forest pixels, increasing the contrast in the forest region. The authors suggested the higher resolution and the narrow bandwidths accounted for the dramatic contrasts between the image data sets.

(1) Spectral plot comparisons of the multispectral bands for different ground targets (grass, water, urban features, and forest) illustrating the relationship between reflectance and wavelength indicated a close match between the two sensors. The spectral plots were created by the selection of training pixels for each target group. ALI spectral values were closer in value than those seen in the ETM+ data; again, this is a result of the narrow bandwidths and higher resolution. The only notable difference in the spectral response between the two sensors was evident in band 5 for grass and urban features. These targets had up to 20% variation in signal response between the sensors. Specifically, the ALI band 5 with a reflectance of 0.35 μm is ~20% higher than the ETM+ value of 0.29 μm .

(2) The combined spectral plot of data from ETM+, ALI, Hyperion, and the empirically derived SAIL show overall an excellent agreement. The three satellite data sets closely match one another, with slightly different values recorded in the SAIL model data. SAIL values best matched those of the sensors in the visible portion of the spectrum.

f. Conclusions. The authors of this study were able to establish a simple, multi-layer canopy reflectance model using measured parameters from the site to compare the ETM+ and ALI spectra. Hyperspectral data were also compared against the satellite and ground data. Additional work is needed to establish the relationship between leaf area index (LAI)

and satellite data. The potential use of ALI and hyperspectral Hyperion for studies of forests in remote locations and forests at risk may greatly enhance forest management and lower the costs associated with ecological monitoring. Accurate estimates of LAI based on satellite imagery have the potential to support forest biomass monitoring, and hence forest health and changes in canopy structure attributable to pollution and climate change. The ability to estimate LAI with remote sensing techniques is, therefore, a valuable tool in modeling the ecological processes occurring within a forest and in predicting ecosystem responses.

6-7 Case Study 5: Blended Spectral Classification Techniques for Mapping Water Surface Transparency and Chlorophyll Concentration

- *Subject Area:* Water quality
- *Purpose:* To establish water clarity and algal growth in a dam reservoir
- *Data Set:* Landsat TM - Visible and infrared

a. Introduction.

(1) An accurate portrayal of water clarity and algal growth in dynamic water bodies can be difficult owing to the heterogeneity of water characteristics. Heterogeneity can stem from the spatial distribution of sediments delivered to a lake by a tributary. Water turbidity associated with tributary sediment load controls water clarity and subsequently will impact algae growth. Additionally, algal growth will influence water clarity by reducing water transparency during times of algal blooms. Both algal growth and sediment turbidity are controlled by such factors as water depth, flow rate, and season.

(2) To better monitor the water quality at dam reservoirs, a spatial estimate of both water clarity and algal chlorophyll over a broad area is required. To accurately capture these properties a large number of water samples must be taken, a task that may not be feasible for most studies. Remote sensing lends itself well to the assessment of water quality testing at a variety of spectral scales due to the response of suspended sediment in the visible and thermal spectrum. Chlorophyll, produced by algae, can also be detected by its visible and infrared emission. The study reviewed here developed a classification algorithm to predict water clarity and chlorophyll concentrations. The algorithm was based on a correlation between spectral data and the empirical field data. Previous studies attempting to classify water clarity and chlorophyll required field sampled training sites. The goal of this study was to develop an algorithm based on empirical data that would illuminate the need for such test training sites. Thus, researchers testing for water quality would then need only the Landsat TM data to monitor water quality at a fresh water lake.

b. Field Work. Secchi Disk measurements and water samples were collected at a dam reservoir in conjunction with a Landsat fly-over at West-Point Lake, Georgia. Water samples were frozen and stored in a dark room to preserve the algae populations. These samples were later analyzed for chlorophyll (C_a) concentrations. Water clarity was measured *in situ* with a Secchi Disk (S_d). This 20-cm disk estimates water clarity by measuring the depth to

which the disk is visible. Remote sensors generally detect water clarity to 20–50% of the S_d measurement. Sampling sites were chosen evenly across the reservoir and adjacent tributaries. A global positioning unit was used to locate 109 sample sites. Drift during sampling occurred but was compensated for with the use of a 3×3 kernel during image classification. Samples and data were collected during two periods—summer and fall of 1991.

c. Sensor System. Two Landsat TM data sets separated in time were used to develop a linear-logarithmic cluster analysis. Visible, near, and middle infrared radiation band ratio was employed with a stratified sampling technique. Using a variety of band ratio, the workers were able to accurately develop a blended classification scheme, which is detailed below.

d. Study Results. The authors adapted multivariate density estimation with the use of an algorithm k-NN density estimator. This was used to group spectrally similar pixels. The spectral classes and class structures (or groupings that separated the spectral classes) were developed using an unsupervised classification. Within each of the two scenes, 16 unique classes were determined. These classes were combined with the empirical data, leaving four logarithmic algorithms. Applying a 3×3 kernel to the data compensated for the drift that occurred during data collection. This placed the positional accuracy to within ± 30 m.

(1) The average spectral value was determined by a log estimation of the band ratio for the given pixel within the kernel (Equation 6-2). Combinations of band ratios were tested. A middle infrared ratio against the visible red showed the largest correlation with S_d and C_a . Visible green versus near infrared also provided a good separation of the spectral response for estimating S_d and C_a .

$$IR = \frac{1}{9} \sum_{x=1}^3 \sum_{y=1}^3 \ln \frac{(\text{mid IR})}{(\text{visible red})_{x,y}} \quad 6-2$$

(2) Observed versus predicted S_d and C_a were well correlated with the use of this log estimate. Focused sampling and spectral blending led to the development of an accurate unsupervised classification with a 95% confidence interval. Sampling positions near tributaries were overestimated at only five sampling sites (relative to 109 sampling sites).

e. Conclusions. A strong correlation was made between the Landsat TM middle IR and the empirical Secchi Disk and chlorophyll concentrations. Chlorophyll was shown to have increased from 12.64 to 17.03 mg/m³, contributing to a decline in water clarity. The application of this log estimate now eliminates the need to collect empirical water quality data, likely reducing the cost in a water quality survey.

Point of Contact: Robert Bolus, Phone: (603) 646-4307

6-8 Case Study 6: A SPOT Survey of Wild Rice in Northern Minnesota

- *Subject Area:* Agriculture
- *Purpose:* To estimate the percentage of wild rice in a wetland environment
- *Data Set:* Visible and near infrared

a. Introduction.

(1) A vegetation survey of natural wild rice surrounding three neighboring lakes 200 miles (518 km) south of St. Paul, Minnesota, was conducted to provide a base map for pollutant and water level monitoring. The study presented here utilized standard supervised classification, based on ground-truth, of high-resolution SPOT data. Wild rice is a natural marsh grass that is sensitive to water level changes and to changes in phosphorous concentrations; increases in phosphorous and water levels can significantly destroy wild rice communities. This is of concern as this important grass is a staple in the Chippewa Indian diet and is consumed by migratory birds.

(2) The researchers in this study were tasked with mapping and estimating the acreage of wild rice surrounding three lakes in Minnesota. Three spectral classes were developed with the use of a supervised classification to delineate the grass and its varying substrate.

b. Description of Methods. Ground truth data were collected simultaneously with SPOT over flight. The ground truth data included information regarding vegetation and substrate type as well as the sites corresponding UTM (global position in the Universal Transverse Mercator coordinate system).

c. Field Work. In the field, 18 ground control points (GCPs) were collected for rectification of the SPOT image and an additional 132 ground truth points were collected for the supervised classification algorithm. This data collection coincided with the SPOT over flight.

d. Sensor System. SPOT was chosen for its optimal detection of vegetation in the presence of inorganic ground cover (i.e., water). Vegetation absorbs both red and blue radiation, while reflecting green and near infrared (NIR) because of chlorophyll production. This matched well with the spectrum data provided by SPOT (which maintains green, red, and NIR bands among others).

e. Study Results.

(1) Prior to the classification process, it had been predicted that the wild rice would dominate one spectral class, as wild rice is spectrally distinct from other vegetation. Openings in the grass canopy, however, contributed to the spectral mixing observed in the image scene. Three spectrally distinct populations were noted, likely because of the heterogeneity of the background reflectance, varying crop canopy, and varying water content in the substrate.

(2) A histogram plot of the digital number value assigned to each pixel in the scene clearly reveals three distinct spectral populations. These three classes were determined to be wild rice growing in the lake, wild rice in marsh, and wild rice in a saturated soil. Wild rice growing in shallow or marsh water produced pixels that overlapped with more than one class. The near-infrared (N-IR) band allowed for better spectral separation by eliminating the effect of varying amounts of water in the substrate.

f. Conclusions.

(1) An estimate of the acreage percent based on a supervised classification determined that 1% of the scene was dominated by wild rice. Habitat was shown to predominately exist along the lakeshore, at inlets, ponds, on banks, and in marsh areas. Wild rice was determined to grow in saturated soil, marsh, and in shallow lake waters. The author recommend 200 ground truth points be collected per class (100 for spectral determinations and 100 for classification designation). Application of the ground truth data to a SPOT scene collected 5 days after the ground truth data did not produce an accurate classification. This test reveals the limitations on the usefulness of SPOT data for surveying vegetation—ground truth must be collected at the time of data acquisition.

(2) A detailed map of the distribution of wild rice will allow land managers to better predict the impact of changes in water level and phosphorous input on the natural production of wild rice.

Point of Contact: Robert Bolus, Phone: (603) 646-4307

6-9 Case Study 7: Duration and Frequency of Ponded Water on Arid Southwestern Playas

- *Subject Area:* Hydrology.
- *Purpose:* To delineate playa inundation frequency and duration.
- *Data Set:* Multispectral/thermal (Landsat 4, 5, and 7 and MTI – Multi-spectral Thermal Imager).

a. Introduction.

(1) Playas are ephemeral shallow lakes found in the arid southwest United States. Their hydrology is dominated by rainfall and runoff in the wet season and evaporation throughout most of the year. Surface hydrology, particularly frequency and duration, is poorly understood in the playa environment. US waters, including playa water, are Federally regulated under article 33 CFR 328.3 [a] of the *Clean Water Act*. Water bodies are delineated to their outermost extent termed their “Ordinary High Water” (OHW). OHW is defined by the presence of physical hydrological features representing the ordinary reaches of high water in its bed or basin.

(2) Playas exhibit tremendous temporal variation, as they may not pond at all during a particular year or may remain ponded for several years. The extent to which water remains

on the surface is influenced by the ambient climate, surface properties, evaporation rate, salinity, and infiltration or discharge of groundwater. Spatial and temporal factors such as inundation, evaporative rate, relocation of brine pools by winds, and desiccation of surface water hinder the ability to approximate the duration and frequency of ponding necessary to accurately model flood events or to determine whether certain Federal environmental regulations apply. This study attempted to model the frequency and duration of playa inundation in an effort to better delineate playas for regulations.

b. Description of Methods.

(1) For this study, three playa lakes on the Edwards Air Force Base were examined with the use of 20 years of historical Landsat and MTI imagery. These data were coupled with 59 years of precipitation records collected on the base. Rogers Lake (114 km²) and Rosamond Lake (53 km²) occupy the eastern and western region of the study area, respectively. Smaller playa lakes separate Rogers and Rosamond Lakes, including Buckland (5 km²). The playa lakes are located on a Pleistocene glacial lakebed; the Pleistocene features dwarf the present geologic structures. Chenopod vegetation and saltbush plant communities dominate the terrestrial plain surrounding the playa.

(2) The playas remain dry for most of the year; however, winter rainstorms and summer thunderstorms cause water to periodically inundate playas. The duration of flooding depends on the magnitude and location of precipitation and ambient prevailing climate. Significant flooding is also associated with El Niño events in the Pacific Ocean, which leads to above-normal precipitation in the Southwestern US. Precipitation records maintained at Edwards Air Force Base provided precipitation data for the years 1942 to 2001. The average annual precipitation was calculated to be 13 cm/year with an estimated 280cm/year evaporation rate.

c. Sensor System. The department of energy on collected visible and near infrared data with the use of a Multi-spectral Thermal Imager (MTI) from February through May of 2001. Two sequential daily MTI images were acquired at 16-day intervals. This was done to ensure the capture of water that may exist at any time throughout the course of 31 days. The acquisition of multiple scenes eliminated the lack of data due to cloud coverage. Seven years of data were analyzed for this inundation study.

d. Study Results.

(1) The visible bands were not useful in visually delineating ponded water. Ponded water was best defined by a band ratio technique of B5/B2, which evaluated the proportion of reflective energy to input energy. The ratio values for each pixel were consistently greater than 1.0 for non-water objects and less than 1.0 for water objects. This ratio method was then followed by a classification that grouped pixels with values less than 1.0. Workers then assigned a DN value of 0 for objects displaying a ratio value of less than 1.0, thereby coloring all water bodies black in the scene. This ratio technique aided the image analysis by eliminating the problems caused by sun angle, sun intensity, and seasons—problems intrinsic to multi-temporal image analysis.

(2) The average precipitation was calculated to be 8.28 cm/year. These data, coupled with the image data, established the inundation frequency to be 51% of the time. This suggests that the playas are inundated, on average, every other year.

e. Conclusions. Results indicate that ponding that persists 16 days or longer occurred approximately every other year. The average precipitation needed to initiate ponding is estimated at 8.29 cm. Duration of ponding was shown to range from 1 to 32 weeks, with a direct relationship between length of inundation and total seasonal rainfall. Playa inundation, duration, and frequency can be determined from precipitation data and satellite imagery. The authors suggest the addition of contributing factors such as soil type and geometry may lead to a more robust hydrologic model of the playa system. A thorough understanding of the playa hydrologic regime may one day lead to new land use regulations.

Point of Contact: Robert Lichvar, Phone: (603) 634-4657

6-10 Case Study 8: An Integrated Approach for Assessment of Levees in the Lower Rio Grande Valley

- *Subject Area:* Engineering.
- *Purpose:* To detect weak areas within levees prior to flood events.
- *Data Set:* LIDAR.

a. Introduction. A series of levees were constructed along the Lower Rio Grande in Texas and Mexico in the 1930s. Local farmers, working with the county government, constructed the levee system to prevent flood damage to crops in low-lying areas near the river. The levees were constructed of sediment and soil materials obtained locally. The Federal government later completed the levee system in the 1940s and continued expansion and repairs through the 1940s. The US Army Engineer Research and Development (ERDC), working recently with the International Boundary and Water Commission, developed a GIS database to catalog levee condition. Knowledge of levee conditions prior to a flood is helpful in determining where repair and rebuilding are necessary on these man-made structures. A visual display of the levee and detail on the location of potential structural failure could then be used to prioritize levee repair and reconstruction.

b. Description of Methods.

(1) This study maintained four primary objectives. The first was to survey the levee system of the Lower Rio Grande River. The information compiled during the course of this survey was organized into a GIS database. The second was to extensively evaluate levee condition. The third was to compare the results of the airborne survey with those obtained from ground-based surveys. This objective tested the validity of implementing a remote sensing survey. Fourth, ground-truth locations were selected based on LIDAR data, and at these locations soil and subsurface strata were mapped using a cone penetrometer.

(2) In the course of developing the GIS database, ERDC developed a 10-point criterion for evaluating the condition of the levee system. Traditional geophysical tools were

then merged with remote sensing methods to proceed with the levee assessment. Levee topology was assessed with the use of LIDAR, digital video, aerial photographs, soil maps, and geological maps. Topographic deviations of 6 in (15.2 cm) or more along the centerline of the levee were then targeted for detailed seismic field studies. In addition to targeting segments with an undulating topography, several stretches of the levee (on the US side) were seismically surveyed.

c. Field Work.

(1) Ground surveys were conducted at five sites ranging in length from 3000 to 5000 ft (0.91 to 1.5 km). Electrical resistivity, EM, and magnetic surveys were collected in conjunction with the airborne EM and magnetic survey. The ground-based geophysical sites were geo-referenced with the use of a global position unit.

(2) Much of the data acquired for the GIS database were collected from previous sources. Information was taken from state and Federal survey maps, and from new and old aerial photographs. Digital photography and aerial photographs were used to map Holocene and Pleistocene deposits and geomorphologic structures. In areas with recent urban development, older images dating to the 1930s were used to evaluate the underlying geology.

d. Sensor Data Acquisition. LIDAR was utilized to survey levee elevation to determine deviations from the original design. Deviations in height indicate segments with potential damage attributable to seepage or sediment voids. Floodwater overtopping, slope failure, and seepage all potentially compromise levee stability. Seepage can create void spaces in the sediment and soil, resulting in subsequent levee collapse.

e. Study Results.

(1) The levee was then mapped and tagged with a conditional assessment of good, marginal, acceptable, or high-risk zones. The assessment was based on a numerical measure of 10 features deemed important in determining levee stability. These 10 features were chosen by agreement among Corps experts specializing in levee construction and repair. Table 6-2 lists the 10 features ranked in order of importance.

(2) Low scores in any one of the 10 features could result in a poor rating for a given levee segment. The levee was divided into segments based on conductivity measurements (shown to be controlled by levee material make-up); each segment was then given a numerical value based on a weighted measure of the 10 features. Segment ratings were color coded and presented as a layer within the GIS database. The color-coded maps provided an easy to interpret assessment of levee condition.

Table 6-2
Factors Important in Levee Stability
Performance history (under flood stage)
Construction history (original or upgraded)
Visual inspection apparent condition (on-site observation)
Material type (sand [worst] transition to clay [best]; (from EM, borings, soil maps)
Topographic irregularity (swags, erosion) (from LIDAR)
Potential slope stability (material type, relation to flow)
Man-made intrusions (utilities, bridges, pump stations, etc.)
Geology (old stream beds, river deposits)
Proximity of borrow area (size, depth, distance, side of levee)
Anomalies (unexplained radical conductivity "spots")

List is modified from Dunbar et al. (2003)

f. Conclusions. LIDAR, accurate to within 2 to 3 in (5.1 to 7.6 cm), was beneficial in economically mapping the surface morphology of the Lower Rio Grande Valley levee system. The merged remote sensing and geophysical data onto a GIS database facilitated easy retrieval of information for individual segments and can continue to aid in the management of the levee system. The authors view this study as a success and acknowledge that the application of these techniques to other geographical regions, while potentially of benefit, may not hold true for levee projects in other regions.

6-11 Case Study 9 : From Wright Flyers to Aerial Thermography—The 1910 Wright Brother's Hangar at Huffman Prairie

- *Subject Area:* Archeology
- *Purpose:* To review developing NASA products and detail their use in Corps works
- *Data Set:* Airborne CAMS

a. Introduction.

(1) The Huffman Prairie Flying Field, a National Historic Landmark located at Wright-Patterson Air Force Base, was surveyed using a variety of ground and airborne sensors in an effort to locate the forgotten Wright Brother's hangar. This hangar, in use from 1910 to 1916, was the training and testing site for the Wright Aeronautical Company activities. The hangar was demolished during the 1940's with no record of its precise location.

(2) In the early 1990s, CERL researchers investigated the Huffman Prairie Flying Field using traditional and common archeological methods, such as excavation, magnetic and electromagnetic surveys, and ground penetrating radar (GPR). NASA aided CERL's effort with the addition of thermal data collected from an airborne platform. The airborne

data isolated a rectangular footprint, which corresponded with the location of the Wright hangar. Later ground truth data collection and excavation works unearthed well-preserved wall posts constructed of wood. This project exemplifies the technological methods currently being adopted by archeologists. Geographic Information Systems (GIS) practices are now in wide use among archeologists, who take advantage of the utility of spatially related data.

b. Description of Methods. This study had two objectives; the first was to locate the precise position of the Wright hangar. In archeological terms, the site and the history centering on the Wright Brother's and their activities is well documented. The historical record contains many photographs and aerial photographs that trace the approximate location of the Wright buildings. In 1994 an architectural firm established the dimensions and structural details of the Wright hangar with the use of these photographs. They determined that the hangar was approximately 70 by 49 ft (21.3 by 14.9 m). Knowing the approximate dimensions and location of the building would seemingly make the archeological work a simple task. The second objective of the study was to determine if traditional and modern archeological work could add insightful information to the already well-documented site, and thereby further detail the history of early American aviation.

(1) The authors describe the general area surrounding the Huffman Prairie Wright Brothers field as being relatively undisturbed despite the growth and development of the Wright-Patterson Air Force Base neighboring the site. The prairie had been subject to burning, but not plowing. The task in locating the hangar included fieldwork, near surface geophysical work, and aerial remote sensing. The initial excavation made it apparent that identifying remains of the hangar would require either a significant amount of additional excavation or the use of technologically sophisticated, noninvasive methods. Further excavation was deemed too destructive for the site, leading to the decision to employ near-surface and aerial remote sensing.

(2) The geophysical work included magnetic, electromagnetic, and ground penetrating radar (GPR). Combining multiple geophysical techniques is a good practice, as one instrument may easily pick up features not identified by another. Geophysical survey methods typically involve data collection in a grid pattern across the study site. Anomalies in the sub-surface potentially indicate natural phenomena or anthropogenic disturbances in the strata. Some anomalies may then be excavated for ground-truth data collection. It is generally good practice to conduct some ground-truth to verify the geophysical interpretations.

c. Field Work.

(1) Fieldwork, prior to collecting the remote sensing, began in 1990. The researchers hoped to find underground building remnants or surface features, such as the hangar's footings or drip lines that paralleled the absent roofline. Long trenches were hand-excavated unearthing 60% industrial debris, 2% domestic articles; the remaining material consisted of wood debris and other uncategorized items. Excavation did not identify any intact architectural remains of the actual building, and did not locate the precise position of the hangar.

(2) Additional fieldwork verifying the geophysical results uncovered three features. Feature 1 was a well-preserved, intact wood post—possibly one of the hangar's major wall

posts. Features 2 and 3 were pits filled with artifacts and debris. Feature 2 fill included nails, a shell casing, and flat glass. The function of this pit was undetermined. Feature 3 contained wood, glass, nails, and roofing fragments. It was assumed that this was a posthole pit excavated in 1924 during the remodel and repair of the hanger. The posthole was subsequently back filled with reconstruction debris. These three features were not evenly spaced nor in a parallel or perpendicular orientation relative to the predicted location of the hanger. The authors did assert that possibly two of these features represented intact hangar posts.

d. Sensor Data Acquisition. The airborne remote sensing study conducted by NASA incorporated a calibrated airborne multispectral sensor (CAMS), which collects data in the visible, infrared, and thermal bands. A hand held inframetrics thermal scanner was also used.

e. Study Results.

(1) The geophysical survey results indicated that a rectangular area defined by the conductivity, magnetic, and GPR anomalies most likely encompassed the hangar location, which was initially indicated by the 1924 air photo. The airborne hand held inframetrics confirmed the shape and location of the hangar. An explanation for the distinct thermal response remains unclear. The authors suggested that soil compaction and heat retention related to spilled petroleum products may account for the unique thermal signature at the hangar site. The field research led to the collection of over 6000 individual samples; the majority of which were buried industrial artifacts. The authors stated that with “no historical records, it might have been very difficult to infer the primary function of the hangar building” from the collected fragments.

(2) All artifacts were georeferenced and a GIS map was generated to indicate the distribution of materials relative to the hangar and other building units. The majority of artifact categories are concentrated on the northern portion of the hangar as a result of demolition processes. The inframetrics was useful in locating the hangar footprint and delineated gullies adjacent to the road. The CAMS detected the actual roadbed.

f. Conclusions. This study demonstrates how remote sensing technologies can further traditional research efforts in the area of archeology and history. The amalgamation of GIS with airborne and ground remote sensing methods proved highly successful in providing additional information on the already well-documented site. The distribution mapping of artifacts indicated that the building had been demolished by a bulldozer, differing from the theory that the building had simply collapsed on its own accord. Even though the hangar may have been demolished using a bulldozer, its archaeological evidence maintained some integrity and was easily detected by the thermal sensor. Thermal sensors are thus likely to join the growing array of near surface geophysical and aerial remote sensing techniques that can enhance researchers ability to detect and study archaeological sites.

6-12 Case Study 10: Digital Terrain Modeling and Distributed Soil Erosion Simulation/Measurement for Minimizing Environmental Impact of Military Training

- *Subject Area:* DEM generation and soil erosion modeling
- *Purpose:* To adequately model soil erosion and transport for land use management
- *Data Set:* Digital Elevation Models (DEM)

a. Introduction.

(1) The conservation of soil on military land is a priority among land use managers, second only to the protection of threatened and endangered species. A realistic model of soil erosion and subsequent transport will provide managers the information required to better plan military activities, such as training. A better model of the various factors that contribute to soil loss will give insight into the best temporal and spatial use of military land.

(2) The optimal soil loss model incorporates information regarding the diurnal, seasonal, and temporary elements influencing soil properties, as well as incorporating terrain details. Prior to this 1997 study, soil loss models tended to measure soil loss along a linear slope, calculated as the average slope across the study area. Models with these simple slope inputs do not consider the dynamic nature of slope terrain and its consequential control on soil erosion, transport, and deposition. The study summarized here attempted to improve upon existing soil erosion models by incorporating details associated with an undulating surface. The model extracted high resolution terrain information from a digital elevation model (DEM) to better mimic erosional provenance and sediment sinks within a watershed.

b. *Description of Methods.* This study applied three sediment erosion/deposition models to 30- and 10-m DEM data. The models included CASC2D, a two-dimensional rain-fall/runoff model, USPED, an improved Universal Soil Loss Equation model, and SIMWE (SIMulated Water Erosion), a landscape scale erosion/deposition model. All models attempted to simulate watershed response to military training scenarios.

(1) The first model, the CASC2D is a two-dimensional rainfall-runoff model that simulates spatially variable surface runoff. This modeling process can be found in GIS/remote sensing software packages (http://www.engr.uconn.edu/~ogden/casc2d/casc2d_home.html). Model inputs include runoff hydrographs, and water infiltration rate and depth, surface moisture, surface runoff depth, and channel runoff depth.

(2) The second model, the Revised Universal Soil Loss Equation (RUSLE; see equation 6-3), is the most widely used empirical erosion model, and is best applied to homogeneous, rectangular agricultural fields. The equation quantifies major factors that affect erosion by water. The LS (slope length factor) accounts for only the steepness of the terrain over a given area. The authors of this study developed an LS analog for the RUSLE and refined the soil loss equation creating the Unit Stream Power Erosion and Deposition

(USPED) model. This model increases the accuracy of erosion and deposition prediction on uneven terrain.

$$A = R \times K \times LS \times C \times P \quad 6-3$$

where

- A = estimated average soil loss in tons per acre per year
- R = rainfall-runoff erosivity factor
- K = soil erodibility factor
- LS = slope length factor
- C = cover-management factor
- P = support practice factor.

(3) See <http://www.iwr.msu.edu/rusle/about.htm> for details on the Revised Universal Soil-Loss Equation.

(4) The two models described above use statistical averages of hill slope segments for the entire watershed, leading to inaccurate outputs. The SIMulated Water Erosion (SIMWE) model, the third model used in this study, overcomes these shortcomings by adding a continuity equation. SIMWE is based on the solution of the continuity equation (solved by Green's function Monte Carlo Method) that describes the flow of sediment over the landscape area. The factors included in the SIMWE model include measurements relating to steady-state water flow, detachment and transport capacities, and properties of soil and ground cover. The primary advantage of this model is its ability to predict erosion and deposition on a complex terrain on a landscape-scale, thereby improving land use assessments.

c. Remotely Sensed DEM Data. In an effort to minimize environmental impacts at military training sites, CERL scientists evaluated the effectiveness of applying standard soil loss equations with the use of DEM at varying resolutions. The optimal pixel size for landscape level erosion and deposition modeling ranges from 5 to 20 m. Most readily available DEM data is at the 30-m resolution. Higher resolution DEM data are slowly becoming more available ; for older DEM data sets and the easily accessible Landsat data, it is possible to interpolate the low resolution data and resample the data at a finer resolution. For this study the authors converted 30-m resolution data to 10-m resolution data by applying a regularized spline with tension (RST) method, a spatial interpolation tool included in some GIS software. The method is a smoothing function, which interpolates the resampled data from scattered data (RST was developed by Lubos Mitas at North Carolina State University).

d. Study Results. The authors illustrated the issues associated with modeling soil loss over a large area by evaluating a mountainous, 3000-km² region in Fort Irwin, California. Topographic inputs into the models served as both a tool in evaluating erosion potential and in determining the quality of the DEM. Low quality DEMs hold a high proportion of noise in the data. The noise in the data creates two related problems: 1) the signals could easily be interpreted as landscape features, and 2) large terrain features could be obscured by the noise. Resampling and smoothing techniques using the RST reduced the noise and produced a 10-m resolution DEM. This process better highlighted prominent topographic features.

(1) The potential for net erosion/deposition was calculated using two different resolutions (the 30-m DEM and a 10-m DEM developed by the resampling of the 30-m data).

These calculations provided the test required to determine the effectiveness of the smoothing and resampling techniques. The visual analysis of the image overlaid onto the 10-m resolution DEM revealed little noise. The USPED model is described as being “very sensitive to artifacts in a DEM as it is a function of second order derivatives (curvatures) of the elevation surface.” With the reduced noise in the data, the USPED model is predicted to accurately assess soil erosion and deposition.

(2) Sediment flow rates were calculated for a subset area from within a 36-km² area of Fort McCoy, Wisconsin. The rate was determined with the use of the SIMWE, which solves for the continuity of mass equation. The results indicated high sediment flow rates in valley centers and varying flow rates in adjacent areas. The SIMWE model compared well with the USPED model results

(3) The USPED and SIMWE models were also compared in an analysis of soil transport in the Fort McCoy, Wisconsin, area. Topographic potential for erosion and deposition were estimated with the USPED model using a 30-m and a 10-m DEM. The 10-m data were again derived from the 30-m data by a smoothing and resampling technique.

(4) The GIS map is based on the 10-m data denoting areas of high potential for soil erosion, typically shown to be hilly areas adjacent to streams. This landscape model showed areas of temporary deposition, where soil and sediment resided before entering the main stream. The map created with the 30-m data inadequately predicted the areas of soil loss; it was suggested this was the result of concentrated flow in valleys. Furthermore, artificial waves of erosion and deposition were shown in flat areas. This was due to the vertical resolution of up to 1 m in the 30-m pixel size DEM. The 10-m data maintains a lower 0.1-m vertical resolution.

(5) When the 10-m resolution DEM was used with the USPED model, intense erosion was predicted in the hilly regions adjacent the main streams and tributaries. Deposition continued to be evident in the concave areas. Distinct from the map derived with 30-m DEM, the 10-m resolution DEM GIS map indicated high erosion in areas with concentrated flow that could reach the main streams. The artificial pattern of erosion/deposition along nearly flat contours was not depicted in the 10-m GIS data.

e. Conclusions. The CASC2D, USPED, and SIMWE soil erosion models significantly advanced the simulation of runoff, erosion, and sediment transport and deposition. With the application of factors relating to three dimensions, these models better predict the spatial distribution and motion of soil and sediments in a watershed. The 10-m resolution was shown to be most advantageous in revealing the detail required to model soil erosion and deposition. The 10 m resolution was easily developed from 30-m pixel sized data with the use of software resampling tools followed by a smoothing algorithm. In summary, this work potentially improves land management and should reduce land maintenance and restoration costs.

Appendix B

Regions of the Electromagnetic Spectrum and Useful TM Band Combinations

Spectrum Region	Wavelength range	Use	
UV	0.300 – 0.446 μm	Florescent materials such as hydrocarbons and rocks. Monitor ozone in stratosphere	
Visible - blue	0.446 – 0.500 μm	Soil/vegetation discrimination, ocean productivity, cloud cover, precipitation, snow, and ice cover	Urban features
Visible - green	0.500 – 0.578 μm	Corresponds to the green reflectance of healthy vegetation and sediment in water.	
Visible - red	0.579 – 0.7 μm	Helpful in distinguishing healthy vegetation, plant species, and soil/geological boundary mapping	
Near infrared (NIR)	0.7 – 0.80 μm	Delineates healthy verses unhealthy or fallow vegetation, vegetation biomass, crop identification (near infrared) soil, and rocks	Surface water, snow, and ice
	0.80 – 1.10 μm	Delineates vegetation, penetrating haze and water/land boundary mapping	
Mid-infrared	1.60 – 1.71 μm (SWIR)	Soil and leaf moisture; can discriminate clouds, snow, and ice. Used to remove the effects of thin clouds and smoke	
	2.01 – 2.40 μm	Geologic mapping and plant and soil moisture, particularly useful for mapping hydrothermally altered rocks	
Thermal IR	3.0 – 100 μm	Monitoring temperature variations in land, water, ice, and forest fires (and volcanic fire)	
	6.7 – 7.02 μm	Upper-tropospheric water vapor	
	10.4 – 12.5 μm	Vegetation classification, and plant stress analysis, soil moisture and geothermal activity mapping, cloud top and sea surface temperatures.	
Microwave	1 μm to 1 m	Useful for mapping soil moisture, sea ice, currents, and surface winds, snow wetness, profile measurements of atmospheric ozone and water vapor, detection of oil slicks	

	Color Plane			Applications
	Red	Green	Blue	
Landsat TM Band Combination	3	2	1	True Color. Water depth, smoke plumes visible
	4	3	2	Similar to IR photography. Vegetation is red, urban areas appear blue. Land/water boundaries are defined but water depth is visible as well.
	4	5	3	Land/water boundaries appear distinct. Wetter soil appears darker.
	7	4	2	Algae appear light blue. Conifers are darker than deciduous
	6	2	1	Highlights water temperature.
	7	3	1	Helps to discriminate mineral groups. Saline deposits appear white, rivers are dark blue.
	4	5	7	Mineral differentiation.
	7	2	1	Useful for mapping oil spills. Oil appears red on a dark background.
	7	5	4	Identifies flowing lava as red/yellow. Hot lava appears yellow. Outgassing appears as faint pink.

Appendix C
Paper model of the color cube/space

To generate the color cube/space cut along perimeter and fold at horizontal and vertical lines. Cube edges will need to be adhered with tape.

Appendix D: Satellite Sensors

Satellites and sensors are commissioned and deployed annually. The list presented here is an attempt to briefly review the utility of only a few sensors. This list, though not fully comprehensive, is a good starting point in referencing sensors.

For an extensive list of satellite sensors (acronyms and full names) see
http://ioc.unesco.org/oceanteacher/resourcekit/M3/Data/Measurements/Instrumentation/gcmd_sensors.htm.

Sensor	Spatial Resolution (metric)	Band/Wavelength or Frequency Detection	Application	URL
AATSR	1000m	0.555µm (green), 0.659µm (red), 0.865µm (NIR), 1.6µm (SWIR), 3.7µm (TIR), 10.85µm (TIR), 12.0µm (TIR)	Atmosphere, forest, vegetation, oceans, coasts, weather & climate	http://telsat.belspo.be/satellites/satellitresult.asp?var=56
AC	250	0.89-1.58µm	Used to atmospherically correct high-spatial, low-spectral resolution multispectral sensors	http://eo1.gsfc.nasa.gov/Technology/AtmosCorr.htm
ACE-FTS	0.02-1cm 4km vertical resolution	2-13 µm (infrared)	Measures the temperature, vertical distribution of trace gases and aerosols and thin clouds	http://www.space.gc.ca/asc/eng/csa_sectors/space_science/atmospheric/scisat/fts.asp
AIRS		Measures 2,300 spectral channels: 0.4 - 1.7 µm and 3.4 - 15.4 µm	Weather, climate, O ₃ , and greenhouse gasses	http://telsat.belspo.be/satellites/satellitresult.asp?var=92
ALI	30 m (10 m – panchromatic)	10 bands across 0.433-2.35 µm	Land use studies, mineral resource assessment, coastal processes research and climate change studies	http://eo1.gsfc.nasa.gov/miscPages/TechForum3.html

Appendix G

TEC's Imagery Office (TIO)

The following is taken from Appendix I of the Geospatial Engineer Manual (EM 1110-1-2902), which outlines the procedures for acquiring image data.

G-1 Development of TEC's Imagery Office (TIO).

a. To help Army agencies/organizations avoid duplicating commercial and civil imagery purchases, the Office of the Assistant Chief of Engineers designated TEC in 1990 to act as the U.S. Army Commercial and Civil Imagery (C2I) Acquisition Program Manager. To accomplish this task, the TIO was initiated with the added focus on educating the soldier on the uses, types, and availability of commercial satellite imagery. As Army use of this imagery increased and as the number of satellites increased, the TIO has grown to keep up with the demand. Currently, TIO provides thousands of dollars of imagery support to its customers, and is an active participant in National Imagery and Mapping Agency's Commercial Imagery Strategy.

b. TIO is the designated repository of selected commercial satellite imagery data pertaining to terrain analysis and water resources operations worldwide. These data support worldwide military applications and operations. TIO executes the Commercial Imagery Program for TEC and the Army. The current revision of Army Regulation 115-11, "Geospatial Information and Services," strengthens the role of TIO as the point of contact for acquisition of commercial satellite imagery in the Army.

G-2 How to Order Commercial Satellite Imagery.

a. USACE Commands are required to first coordinate with TIO before purchasing satellite imagery from a commercial vendor. USACE organizations with requirements for commercial satellite imagery must forward requests to TIO for research, acquisition, and distribution of the data. The requests can be submitted as follows:

TIO@tec.army.mil

Telephone: 703-428-6909

Fax: 703-428-8176

Online Request Form

www.tec.army.mil/forms/csiform1.html

b. Each request should include the following information:

- Geographic area of interest. Please provide Upper Left and Lower Right coordinates (e.g., 27 00 00N 087 00 00W) and path/row, if known.
- Acceptable date range for data coverage (e.g., 5 January 1999 to 3 March 2000).
- Cloud cover and quality restrictions (e.g., less than 10 percent cloud cover, no haze, 10 degrees off nadir).

- Satellite system/sensor. (For basic satellite information, access www.tec.army.mil/TIO/satlink.htm.)
- Desired end product (digital or hard copy and preferred media type; e.g., CD-ROM).
- Point of contact, mailing and electronic address, and telephone number.

c. Purchased Commercial Satellite Imagery Submission to the Commercial Satellite Imagery Library (CSIL)

d. Commercial satellite imagery that the TIO purchases for customers is disseminated upon receipt to the requestor as well as to the CSIL. This provides data access for DoD/Title 50 users.

Appendix H

Example Contract - Statement of Work (SOW)

Laser Fluorescence Oil Spill Surveillance

Statement of Work

2/14/96

To: DOE/NV Remote Sensing Laboratory
From: RSGISC, U. S. Army Corps of Engineers

1.0 Purpose

The purpose of this SOW is to demonstrate proof-of-concept of an airborne fluorescence imaging system capable of sensing oil on land and in wetlands. These are issues of concern to the Corps.

2.0 Background

The U.S. Coast Guard Research and Development Center (R&D Center) and Environment Canada have sponsored experiments with a Laser Environmental Airborne Fluorimeter (LEAF) spot sensor for the detection of oil on water in land-locked pools. The tests successfully demonstrated that oils fluoresce with distinct spectral signatures when excited by a laser source.

In order to develop the fluorescence concept into a practical field instrument for supporting oil spill response operations, an upgrade to an imaging sensor is necessary. The EG&G, Santa Barbara, Special Technologies Laboratory (STL) is prototyping an airborne Laser Induced Fluorescence Imager (LIFI) which can be applied to the detection of oil spills on land and in wetlands.

3.0 Objectives/ Scope

The DOE/NV Remote Sensing Laboratory (RSL) and STL will design and perform measurements to test airborne LIFI technology for the detection of oil-on-land and in wetlands.

1. Acquire laboratory and ground fluorescence spectra of several types of spilled oil on land and in wetlands in the presence of both organic and inorganic background materials. This can be used to define the source intensity needed for required signal levels and resolve major technical issues such as spatial resolution, swath width, aircraft altitude, and speed.

2. Acquire imagery from airborne LIFI over oiled targets for proof of concept.

4.0 Requirements

Task 1

A series of laboratory measurements will be collected to measure the fundamental fluorescence properties of the oils and background materials. Optimal sensing specification for oils depend on the fluorescence efficiency of the oil as well as the spectral and spatial resolution required for the application.

Task 2

Outdoor laser range measurements will be made for up to 20 target/background combinations. These should include crude, diesel and home heating oils, on sand, gravel, soil and vegetation organic backgrounds. Measurements will address the fluorescence efficiency, emission spectra, duration and the effects of oil aging over a period of up to six weeks. The effects of the wetness of the backgrounds on the emission efficiency, duration and spectra will be addressed.

Task 3

When the STL LIFI system becomes airborne, imagery from flight tests over oil targets will be collected. It is planned to operate at an altitude of 300 ft agl and provide a swath of 60 ft., 512 pixels wide or about 1.4 in. per pixel in the cross track direction. The spectral range will be 300nm with 128 channels covering the visible portion of the spectrum. Excitation will be at 355nm.

5.0 Schedule

The STL shall coordinate its airborne data collection schedule to coincide with its other sponsored flight test programs. All ground data will be collected preliminary to airborne testing. All reports and deliverables will be completed within six months of data collection.

6.0 Deliverables

Deliverable 1 - Presentation at Oil Spill Program Review

Test planning will be presented at the Oil Spill Program review and meetings required by the Oil Spill Program Manager [FY96].

Deliverable 2 - Technical Report

A written summary report will be delivered to the Oil Spill Program Manager NLT six months after acquisition of the data.

Deliverable 3 - Distribution of Data

All laboratory, ground and airborne data will become the property of and be transmitted to the RS/GIS Center in digital computer compatible format.

Appendix I
Example Acquisition – Memorandum of Understanding (MOU)

CONDITIONS FOR DATA ACQUISITION DURING
THE 1999 AIG HYMAP USA GROUPSHOOT CAMPAIGN

This Memorandum of Understanding, Conditions for Data Acquisition During the 1999 AIG HyMap USA Groupshoot Campaign (MOU) is entered into between Analytical Imaging and Geophysics LLC ("AIG") a limited liability company, with its principal place of business located at 4450 Arapahoe Avenue, Suite 100, Boulder, Colorado, 80303, USA, and _____ ("Sponsor"), a _____ corporation, with its principal place of business located at _____.

WHEREAS, AIG is acting as the coordinator for various Sponsors for the acquisition of HyMap data, the 1999 AIG/HYVISTA North American Group Shoot ("Group Shoot"), and the Sponsor is will to acquire data using the HyMap sensor system.

WHEREAS, this MOU outlines the conditions for HyMap data acquisition as part of the Group Shoot. It establishes the guidelines for AIG and HyVista Corporation ("HyVista") efforts to acquire data using the HyMap sensor system for sponsor-specified flight locations.

NOW, THEREFORE, in consideration of the premises and the agreements and covenants of the parties set forth in this Agreement, the parties hereto agree as follows:

DEFINITIONS

As used in this Agreement, the following terms have the following meanings:

"Individual Site" means: a 2.3 kilometer wide x 20 kilometer long area.

"Scene" means: an image cube of an Individual Site (2.3 kilometers by 20 kilometers) at 5 meter spatial resolution and 126 spectral bands.

"Research Mode" means: Scenes acquired which may be available to anyone.

"Proprietary Mode" means: Scenes acquired which are only available to the Sponsor ordering acquisition.

OBLIGATIONS OF AIG

AIG shall use its best efforts to perform the services and deliver the group Scene and the Sponsor's Scene(s), listed in Exhibit A, within 8 weeks after completion of the mission. All work shall be performed in a workmanlike and professional manner to industry standards. All work will be performed using AIG facilities,

excepting HyMap data acquisition and items below indicated by (HyVista), which will be performed by HyVista Corporation.

AIG agrees to supply the following for each Scene either on CDs or tape:

- Image data in units of radiance ($\mu\text{W}/\text{cm}^2/\text{nm}/\text{sr}$); BIL format data files with corresponding ENVI header files (HyVista)
- GPS positions of the plane during data acquisition (HyVista)
- Dark current measurements (HyVista)
- Spectral calibration parameters: band centers and band shape (HyVista)
- Image data corrected to apparent reflectance using an atmospheric model; BIL format data files with corresponding ENVI header files
- A single-band image of precision geocorrected data
- Geocorrection information sufficient to precision geocode other bands/results

OBLIGATIONS OF SPONSOR

Sponsors shall supply the start and finish coordinates of each Individual Site in latitude/longitude pairs (decimal degrees using the WGS84 datum). Larger areas can be covered at an incremental cost. If such areas are to be covered, in order to provide uninterrupted coverage of adjacent data strips, a 20% overlap for each strip with its neighbor should be allowed. AIG and HyVista Corporation accept no responsibility for sponsors supplying incorrect coordinates for survey sites; sponsors will be charged in full for the full data acquisition fee in these instances.

DATA ACQUISITION

Data will be acquired at a date nominated by AIG and HyVista with input from the Sponsor. Data will be acquired in weather conditions to the satisfaction of AIG and HyVista. Sponsor will be notified of proposed acquisition of data from an elected study site not less than 24 hours prior to acquisition. AIG and HyVista reserve the right to omit data acquisition for a Sponsor's chosen site if adverse weather conditions preclude the acquisition of data to corporate quality standards.

DATA QUALITY

All data presented to Sponsor shall bear full 126-channel coverage. To keep turbulence effects to a minimum the scanner is mounted on a stabilized platform the Jena SM 2000. The geometric integrity of the data therefore will be within the platform performance characteristics as supplied by the manufacturers and the operators will endeavor to keep turbulence effects to a minimum or abort the line if the motion is too great. Cloud cover will be less than 10 percent total for a named study area. Spatial accuracy of the data is limited by the on-board GPS of the aircraft.

Should a sponsor be dissatisfied with the data quality, the following procedure will be followed: The data in question will be supplied for a quality control assessment to 2 impartial experts, one selected by each

party. The impartial experts will have no professional or financial interest in their selector's organization. The impartial experts will assess the data quality, and judge whether the data is supplied in accordance to HyVista's specifications for the survey. Should the experts judge that data meets or exceeds HyVista's quoted data quality specifications, then the data will be supplied and the sponsor will be liable to pay agreed data acquisition costs, and all costs incurred in the data assessment. Should the experts judge that the supplied data does not meet HyVista's quoted data quality specifications, then the data will not be supplied.

PAYMENT

The cost of a Research Mode Scene is Five Thousand US Dollars (\$5,000.00). The cost of a Proprietary Mode Scene is Ten Thousand US Dollars (\$10,000.00). The Group Shoot Scene is also delivered to the Sponsor at no additional cost. Custom acquisitions and larger areas can be covered at an incremental cost and volume discounts may be applied. These additional Scenes shall be listed in Appendix E.

Invoices will be issued upon signature of this MOU and payment is net 30 days. In instances where AIG and HyVista acquire only a portion of a requested block of data due to adverse weather conditions or other unforeseen circumstances, AIG and HyVista will refund a portion of the fee at a rate proportional to the agreed fee for full data coverage. In the event that no Sponsor data are acquired AIG will refund Sponsor all payments received.

POINTS OF CONTACT

Dr. Fred A. Kruse is designated as the AIG point of contact for this program.

TERM AND TERMINATION

The Agreement shall enter into force on the Effective Date and shall continue until terminated as provided in this Section 8. After all Scenes have been delivered to Sponsor and payment received this Agreement shall terminate.

CONFIDENTIALITY

Both Sponsor and AIG acknowledge and agree that both parties own confidential, proprietary and secret information related to various aspects of Sponsor's and AIG's respective business and technology.

As used in this Agreement, "Confidential Information" consists of (i) any information designated by either party as confidential, and (ii) any information relating to either party's product plans, client lists, product designs, product costs, product prices, product names, finances, marketing plans, business opportunities, personnel, research, development or know-how, except such information which the parties agree in writing is not confidential. Each party shall use the other party's Confidential Information solely for implementing its obligations under this Agreement. Confidential Information shall not include information that (i) is known to each at the time of disclosure to the other party, (ii) has become publicly known through no wrongful act of the other party, (iii) has been rightfully received from a third party authorized to make such disclosure without restriction, or (iv) has been approved for release by written authorization of the other party.

Each party will not use in any way for its own account or the account of any third party, nor disclose to any third party (excepting HyVista), any such Confidential Information revealed to it by the other party. Each party agrees to protect any Confidential

Information from disclosure to others with at least the same degree of care as that which is accorded to its own proprietary information, but in no event with less than reasonable care. In the event of termination of this Agreement, there shall be no use or disclosure by either party of any Confidential Information.

Each party agrees to notify the other party promptly in the event of any breach of confidentiality or security under conditions in which it would appear that any Confidential Information was disclosed in violation of this Agreement, prejudiced or exposed to loss. Each party shall, upon request of the other party, take all reasonable steps necessary to recover any compromised trade secrets disclosed to or placed in the possession of the other party by virtue of this Agreement.

Each party agrees to use Confidential Information under carefully controlled conditions for the purposes set forth in this Agreement, and to inform all persons who are given access to Confidential Information by either party that such materials are confidential trade secrets of the other party. Each party expressly agrees it shall be fully responsible for the conduct of all its employees, contractors, agents and representatives who may in any way breach this Agreement.

Each party acknowledges that any breach of any of its obligations under this Section 7 is likely to cause or threaten irreparable harm to the other party, and, accordingly, each party agrees that in such event, the other party shall be entitled to equitable relief to protect its interest therein, as well as money damages.

WARRANTY AND INDEMNIFICATION

Sponsor shall defend, indemnify and hold harmless AIG from and against all claims, liability, losses, damages and expenses (including attorneys' fees and court costs) arising from or in connection with the use or application of AIG's work by Sponsor or any direct or indirect purchaser or licensee of Sponsor.

AIG SHALL NOT BE LIABLE TO SPONSOR FOR ANY DIRECT, INDIRECT, SPECIAL, AND/OR CONSEQUENTIAL DAMAGES WHATSOEVER, WHETHER CAUSED BY AIG'S NEGLIGENCE, ERRORS, OMISSIONS, STRICT LIABILITY, BREACH OF CONTRACT, BREACH OF WARRANTY OR OTHER CAUSE OR CAUSES WHATSOEVER INCLUDING BUT NOT LIMITED HYVISTA CORPORATIONS INABILITY TO GATHER THE HYMAP DATA SCENES.

GENERAL PROVISIONS

No Assignability. The parties agree that this Agreement is not assignable or transferable by AIG without the prior written consent of Sponsor.

No Agency Relationship. This Agreement does not establish any agency, joint venture, or partnership relationship between the

parties, and neither party can bind the other by any contract or representation.

Notices. All notices provided for in this Agreement shall be in writing and will be deemed effective when either served by personal delivery or sent by express, registered or certified mail, postage prepaid, return receipt requested, to the other party at the corresponding mailing address set forth on the first page hereof or at such other address as such other party may hereafter designate by written notice in the manner aforesaid.

Modification. The parties acknowledge and agree that this Agreement may only be modified by the mutual written agreement of the parties.

Entire Agreement. The written terms and provisions in this Agreement constitute the entire agreement and understanding between the parties relating to the subject matter hereof and supersede all previous communications, proposals, representations, and understandings, whether oral or written, relating thereto. This Agreement may be executed in two or more counterparts, each of which shall be deemed an original and all of which together shall constitute one instrument.

Governing Law. This Agreement shall be governed by and construed and enforced in accordance with the laws of the State of Colorado, U.S.A., without regard to the conflict of laws provisions thereof. Both AIG and Sponsor agree and consent to personal jurisdiction and venue in the state and federal courts in the State of Colorado, U.S.A. All actions relating to or arising out of this Agreement may be brought only in federal or state courts in the State of Colorado, U.S.A.

Binder. This Agreement is binding on and inures to the benefit of the parties, their respective heirs, assigns, and legal representatives.

Severability. In case any one or more of the provisions contained in this Agreement shall, for any reason, be held to be invalid, illegal, or unenforceable in any respect, such invalidity, illegality, or unenforceability shall not affect any other provisions of this Agreement, and this Agreement shall be construed as if such valid, illegal, or unenforceable provision had never been contained herein.

Binding Agreement. Each party agrees and acknowledges that it has read this Agreement, understands it, and agrees to be bound by the terms and conditions herein.

IN WITNESS WHEREOF, this Agreement is executed by and between the parties as of the Effective Date.

Glossary

This glossary was compiled from Internet Sites at the USGS, NASA, Goddard Space Center, Canadian Center for Remote Sensing, and the ASPRS

DISCLAIMER: Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

A

Absolute temperature	Temperature measured on the Kelvin scale, whose base is absolute zero, i.e. -273 °C (0 °C is expressed as 273 °K).
Absorptance	A measure of the ability of a material to absorb EM energy at a specific wavelength.
Absorption band	Wavelength interval within which electromagnetic radiation is absorbed by the atmosphere or by other substances.
Absorptivity	Capacity of a material to absorb incident radiant energy.
Achromatic vision	The perception by the human eye of changes in brightness, often used to describe the perception of monochrome or black and white scenes.
Active remote sensing	Remote sensing methods that provide their own source of electromagnetic radiation to illuminate the terrain. Radar is one example.
Acuity	A measure of human ability to perceive spatial variations in a scene. It varies with the spatial frequency, shape, and contrast of the variations, and depends on whether the scene is colored or monochrome.
Additive primary colors	Blue, green, and red. Filters of these colors transmit the primary color of the filter and absorb the other two colors.
Adiabatic cooling	Refers to decrease in temperature with increasing altitude.
Advanced very high resolution radiometer (AVHRR)	Crosstrack multispectral scanner on a NOAA polar-orbiting satellite that acquires five spectral bands of data (0.55 to 12.50 µm) with a ground resolution cell of 1.1 by 1.1 km.
Aerial magnetic survey	Survey that records variations in the earth's magnetic field.
Aeromagnetic	Aeromagnetic is descriptive of data pertaining to the Earth's magnetic field which has been collected from an airborne sensor.
AGL	Above ground level.
Air base	Ground distance between optical centers of successive overlapping aerial photographs.
Airborne imaging spectrometer (AIS)	Along-track multispectral scanner with spectral bandwidth of 0.01 µm.
Airborne visible and infrared imaging spectrometer (AVIRIS)	Experimental airborne along-track multispectral scanner under development at JPL to acquire 224 images in the spectral region from 0.4 to 2.4 µm.
AID--Agency for International Development	The United States Federal agency for international development projects.
Albedo (A)	Ratio of the amount of electromagnetic energy reflected by a surface to the amount of energy incident upon it.
Albers Equal Area Projection	The Albers Equal Area projection is a method of projection on which the areas of all regions are shown in the same proportion of their true areas. The meridians are equally spaced straight lines converging at a common point, which is normally beyond the pole. The angles between them are less than the true angles. The parallels are unequally spaced concentric circular arcs centered on the point of convergence of the meridians. The meridians are radii of the circular arcs. The poles are normally circular arcs enclosing the same angle as that enclosed by the

other parallels of latitude for a given range of longitude. Albers Equal Area is frequently used in the ellipsoidal form for maps of the United States in the National Atlas of the United States, for thematic maps, and for world atlases. It is also used and recommended for equal-area maps of regions that are predominantly east-west in extent.

Along-track scanner	Scanner with a linear array of detectors oriented normal to flight path. The IFOV of each detector sweeps a path parallel with the flight direction.
Alteration	Changes in color and mineralogy of rocks surrounding a mineral deposit that are caused by the solutions that formed the deposit. Suites of alteration minerals commonly occur in zones.
Amplitude	For waves, the vertical distance from crest to trough.
Analog display	A form of data display in which values are shown in graphic form, such as curves. Differs from digital displays in which values are shown as arrays of numbers.
Analogue image	An image where the continuous variation in the property being sensed is represented by a continuous variation in image tone. In a photograph, this is achieved directly by the grains of photosensitive chemicals in the film; in an electronic scanner, the response in millivolts is transformed to a display on a cathode-ray tube where it may be photographed.
Angular beam width	In radar, the angle subtended in the horizontal plane by the radar beam.
Angular field of view	Angle subtended by lines from a remote sensing system to the outer margins of the strip of terrain that is viewed by the system.
Angular resolving power	Minimum separation between two resolvable targets, expressed as angular separation.
Anomaly	An area on an image that differs from the surrounding, normal area. For example, a concentration of vegetation within a desert scene constitutes an anomaly.
Antenna	Device that transmits and receives microwave and radio energy in radar systems.
Aperture	Opening in a remote sensing system that admits electromagnetic radiation to the film in radar systems.
APL	Applied Physics Laboratory of John Hopkins University.
Apollo	U.S. lunar exploration program of satellites with crews of three astronauts.
Apparent thermal inertia (ATI)	An approximation of thermal inertia calculated as one minus albedo divided by the difference between daytime and nighttime radiant temperatures.
ARC Export	EXPORT creates an ARC/INFO interchange file to transfer coverages, INFO data files, text files, and other ARC/INFO files between various computer systems. An interchange file contains all coverage information and appropriate INFO file information in a fixed length, ASCII format. It can be fully or partially compressed as well as uncompressed ASCII depending upon the given EXPORT option.
ARC SECOND	1/3600th of a degree (1 second) of latitude or longitude.
ARC/INFO	ARC/INFO is a geographic information system (GIS) used to automate, manipulate, analyze, and display geographic data in digital form. ARC/INFO is a proprietary system developed and distributed by the Environmental Systems Research Institute, Inc., in Redlands, California.
ArcUSA	Designed by ESRI, ArcUSA is a general-purpose database used to generate thematic maps of the conterminous United States at the State and county levels. The database contains cartographic information, tabular information, and indices and is designed for a wide range of applications.

Areal	Relating to or involving an area.
Artifact	A feature on an image, which is produced by the optics of the system or by digital image processing, and sometimes masquerades as a real feature.
ASA index	Index of the American Standards Association designating film speed, or sensitivity to light. Higher values indicate higher sensitivity. The ASA index has been replaced by the ISO index.
Ascending node	Direction satellite is traveling relative to the Equator. An ascending node would imply a northbound Equatorial crossing.
ATI	Apparent Thermal Inertia.
Atmosphere	Layer of gases that surrounds some planets.
Atmospheric correction	Image-processing procedure that compensates for effects of selectivity scattered light in multispectral images.
Atmospheric shimmer	An effect produced by the movement of masses of air with different refractive indices, which is most easily seen in the twinkling of stars.
Atmospheric window	Wavelength interval within which the atmosphere readily transmits electromagnetic radiation.
Attributes	Attributes, also called feature codes or classification attributes, are used to describe map information represented by a node, line, or area. For example, an attribute code for an area might identify it to be a lake or swamp; an attribute code for a line might identify a road, railroad, stream, or shoreline.
Attitude	Angular orientation of remote sensing system with respect to a geographic reference system.
AVHRR	Advanced Very High Resolution Radiometer, a multispectral imaging system carried by the TIROS-NOAA series of meteorological satellites.
AVIRIS	Airborne visible and infrared imaging spectrometer.
Azimuth	Geographic orientation of a line given as an angle measured in degrees clockwise from north.
Azimuth direction	In radar images, the direction in which the aircraft is heading. Also called flight direction.
Azimuth resolution	In radar images, the spatial resolution in the azimuth direction.
B	
Background	Area on an image or the terrain that surrounds an area of interest, or target.
Backscatter	In radar, the portion of the microwave energy scattered by the terrain surface directly back toward the antenna.
Backscatter coefficient	A quantitative measure of the intensity of energy returned to a radar antenna from the terrain.
Band	A wavelength interval in the electromagnetic spectrum. For example, in Landsat images the bands designate specific wavelength intervals at which images are acquired.
Bandwidth	The total range of frequency required to pass a specific modulated signal without distortion or loss of data. The ideal bandwidth allows the signal to pass under conditions of maximum AM or FM adjustment. (Too narrow a bandwidth will result in loss of data during modulation peaks. Too wide a bandwidth will pass excessive noise along with the signal.) In FM, radio frequency signal bandwidth is determined by the frequency deviation of the signal.
Base height ratio	Air base divided by aircraft height. This ratio determines vertical exaggeration on stereo models.

Batch processing	Method of data processing in which data and programs are entered into a computer that carries out the entire processing operation with no further instructions.
Bathymetry	Configuration of the seafloor.
Beam	A focused pulse of energy.
BIA--Bureau of Indian Affairs, Department of the Interior	The BIA serves Indian and Alaska Native tribes living on or near reservations. The BIA administers and manages approximately 52 million acres of land held in trust for Indians by the United States and works with local tribal governments on issues including road construction and maintenance, social services, police protection, and economic development.
BIL (Band-Interleaved-by-Line)	BIL is a CCT tape format that stores all bands of satellite data in one image file. Scanlines are sequenced by interleaving all image bands. The CCT header appears once in a set.
Bilinear	The term bilinear is referring to a bilinear interpolation. This is simply an interpolation with two variables instead of one.
Bin	One of a series of equal intervals in a range of data, most commonly employed to describe the divisions in a histogram.
Binary	Based upon the integer two. Binary Code is composed of a combination of entities that can assume one of two possible conditions (0 or 1). An example in binary notation of the digits 111 would represent $(1 \times 2) + (1 \times 2) + (1 \times 2) = 4 + 2 + 1 = 7$.
Bit	Contraction of binary digit, which in digital computing represents an exponent of the base 2.
BIP--Band-Interleaved-by-Pixel	When using the BIP image format, each line of an image is stored sequentially, line 1 all bands, line 2 all bands, etc. For example, the first line of a three-band image would be stored as p1b1, p1b2, p1b3, p2b1, p2b2, p2b3, where p1b1 indicates pixel one, band one, p1b2 indicates pixel one, band two, etc.
Blackbody	An ideal substance that absorbs the entire radiant energy incident on it and emits radiant energy at the maximum possible rate per unit area at each wavelength for any given temperature. No actual substance is a true blackbody, although some substances, such as black lamps, approach this property.
Blind spot	The point of the optic nerve to the retina where no radiation is detected by the eye.
BLM--Bureau of Land Management, Department of the Interior	Under the Federal Land Policy and Management Act of 1976, the BLM administers and manages approximately 300 million acres of public lands primarily located in the western half of the lower 48 States and Alaska. Public lands in the U.S. contain mineral and timber reserves, support habitat for a host of wildlife, and provide recreational opportunities.
BOR--Bureau of Reclamation, Department of the Interior	The BOR was chartered in 1902 with the responsibility to reclaim arid lands in the western U.S. for farming by providing secure, year-around water supplies for irrigation. The BOR's responsibilities since have expanded to include generating hydroelectric power; overseeing municipal and industrial water supplies, river regulation, and flood control; enhancing fish and wildlife habitats; and researching future water and energy requirements.
BPI--Bits Per Inch	The tape density to which the digital data were formatted.
Brightness	Magnitude of the response produced in the eye by light.
Brute Force Radar	See real-aperture radar.
BSQ--Band Sequential	BSQ is a CCT tape format that stores each band of satellite data in one image file for all scanlines in the imagery array. The CCT headers are recorded on each band.
Byte	A group of eight bits of digital data.

C	
Calibration	Process of comparing an instrument's measurements with a standard.
Calorie	Amount of heat required to raise the temperature of 1g of water by 1 °C.
Camouflage detection photographs	Another term for IR color-photograph.
Cardinal point effect	In radar, very bright signatures caused by optimally oriented corner reflectors, such as buildings.
Cartographic	Pertaining to cartography, the art or practice of making charts or maps.
Cathode ray tube (CRT)	A vacuum tube with a phosphorescent screen on which images are displayed by an electron beam.
C band	Radar wavelength region from 3.8 to 7.5 cm.
CCD	Charge-coupled detector.
CCT	Computer-compatible tape.
CD-ROM--Compact Disc-Read Only Memory	CD-ROM is a computer peripheral that employs compact disc technology to store large amounts of data for later retrieval. The capacity of a CD-ROM disk is over 600 megabytes, the equivalent of over 250,000 typewritten pages.
Centerpoint	The optical center of a photograph.
Change-detection images	An image prepared by digitally comparing scenes acquired at different times. The gray tones or colors of each pixel record the amount of difference between the corresponding pixels of the original images.
Channels	A range of wavelength intervals selected from the electromagnetic spectrum.
Charge-coupled detector (CCD)	A device in which electrons are stored at the surface of a semiconductor.
Chlorosis	Yellowing of plant leaves resulting from an imbalance in the iron metabolism caused by excess concentrations of copper, zinc, manganese, or other elements in the plant.
Chromatic vision	The perception by the human eye of changes in hue.
CIR	Color infrared.
Circular scanner	Scanner in which a faceted mirror rotates about a vertical axis to sweep the detector IFOV in a series of circular scan lines on the terrain.
Classification	Process of assigning individual pixels of an image to categories, generally based on spectral reflectance characteristics.
Coastal zone color scanner (CZCS)	A satellite-carried multi-spectral scanner designed to measure chlorophyll concentrations in the oceans.
Coherent radiation	Electromagnetic radiation whose waves are equal in length and are in phase, so that waves at different points in space act in unison, as in laser and synthetic aperture radar.
Color composite image	Color image prepared by projecting individual black-and-white multispectral images, each through a different color filter. When the projected images are superposed, a color composite image results.
Color ratio composite image	Color composite image prepared by combining individual ratio images for a scene using a different color for each ratio image.
Complementary colors	Two primary colors of light (one additive and the other subtractive) that produce white light when added together. Red and cyan are complimentary colors.
Computer-compatible tape (CCT)	The magnetic tape on which the digital data for Landsat MSS and TM images are distributed.
Conduction	Transfer of electromagnetic energy through a solid material by molecular interaction.
Cones	Receptors in the retina, which are sensitive to color. There are cones sensitive to the red, green, and blue components of light.

Contact print	A reproduction from a photographic negative in direct contact with photosensitive paper.
Context	The known environment of a particular feature on an image.
Contrast	The ratio between the energy emitted or reflected by an object and its immediate surroundings.
Contrast enhancement	Image-processing procedure that improves the contrast ratio of images. The original narrow range of digital values is expanded to utilize the full range of available digital values.
Contrast ratio	On an image, the reflectance ratio between the brightest and darkest parts of an image.
Contrast stretching	Expanding a measured range of digital numbers in an image to a larger range, to improve the contrast of the image and its component parts.
Convection	Transfer of heat through the physical movement of matter.
Corner reflector	Cavity formed by two or three smooth planar surfaces intersecting at right angles. Electromagnetic waves entering a corner reflector are reflected directly back toward the source.
Corps	US Army Corps of Engineers (USACE)
COSMIC	Computer Software Management and Information Center, University of Georgia. This facility distributes computer programs developed by U.S. government-funded projects.
Cross polarized	Describes a radar pulse in which the polarization direction of the return is normal to the polarization direction of the transmission. Cross-polarized images may be HV (horizontal transmit, vertical return) or VH (vertical transmit, horizontal return).
Cross track scanner	Scanner in which a faceted mirror rotates about a horizontal axis to sweep the detector IFOV in a series of parallel scan lines oriented normal to the flight direction.
CRT	Cathode ray tube.
Cubic convolution	A high order resampling technique in which the brightness value of a pixel in a corrected image is interpolated from the brightness values of the 16 nearest pixels around the location of the corrected pixel.
Cut off	The digital number in the histogram of a digital image, which is set to zero during contrast stretching. Usually this is a value below which atmospheric scattering makes a major contribution.
CWA	Clean Water Act
Cycle	One complete oscillation of a wave.
CZCS	Coastal Zone color scanner.
D	
Dangling ARC	An arc having the same polygon on both its left and right sides and having at least one node that does not connect to any other arc. See dangling node.
Dangling node	The dangling endpoint of a dangling arc. Often identifies that a polygon does not close properly, that arcs do not connect properly, or that an arc was digitized past its intersection with another arc. In many cases, a dangling node may be acceptable. For example, in a street centerline map, cul-de-sacs are often represented by dangling arcs.
Data collection system (DCS)	On Landsats 1 and 2, the system that acquired information from seismometers, flood gauges, and other measuring devices. These data were relayed to ground receiving stations.

Datum	In surveying, a reference system for computing or correlating the results of surveys. There are two principal types of datums: vertical and horizontal. A vertical datum is a level surface to which heights are referred. In the United States, the generally adopted vertical datum for leveling operations is the national geodetic vertical datums of 1929 (differing slightly from mean sea level). The horizontal datum, used as a reference for position, is defined by: the latitude and longitude of an initial point, the direction of a line between this point and a specified second point, and two dimensions which define the spheroid. In the United States, the initial point for the horizontal datum is located at Meade's Ranch in Kansas.
Defense Meteorological Satellite Program (DMSP)	A U.S. Air Force meteorological satellite program with satellites circling in sun-synchronous orbit. Imagery is collected in the visible- to near-infrared band (0.4 to 1.1 micrometers) and in the thermal-infrared band (about 8 to 13 micrometers) at a resolution of about three kilometers. While some of the data is classified, most unclassified data is available to civilian users.
DEM--Digital Elevation Models	The U.S. Geological Survey produces five primary types of digital elevation model data. They are: 7.5-minute DEM (30- x 30-m data spacing, cast on Universal Transverse Mercator (UTM) projection or 1- x 1-arc-second data spacing). Provides coverage in 7.5- x 7.5-minute blocks. Each product provides the same coverage as a standard USGS 7.5-minute map series quadrangle. Coverage: Contiguous United States, Hawaii, and Puerto Rico. - Degree DEM (3- x 3-arc-second data spacing). Provides coverage in 1- x 1-degree blocks. Two products (three in some regions of Alaska) provide the same coverage as a standard USGS 1-x 2-degree map series quadrangle. The basic elevation model is produced by or for the Defense Mapping Agency (DMA), but is distributed by USGS in the DEM data record format. Coverage: United States 30-minute DEM (2- x 2-arc-second data spacing). Consists of four 15- x 15-minute DEM blocks. Two 30-minute DEMs provide the same coverage as a standard USGS 30- x 60-minute map series quadrangle. Saleable units will be 30- x 30-minute blocks, that is, four 15- x 15-minute DEMs representing one half of a 1:100,000-scale map. Coverage: Contiguous United States, Hawaii. 15-minute Alaska DEM (2- x 3-arc-second data spacing, latitude by longitude). Provides coverage similar to a 15-minute DEM, except that the longitudinal cell limits vary from 20 minutes at the southernmost latitude of Alaska to 36 minutes at the northern most latitude limits of Alaska. Coverage of one DEM will generally correspond to a 1:63,360-scale quadrangle. 7.5-minute Alaska DEM (1- x 2-arc-second data spacing, latitude by longitude). Provides coverage similar to a 7.5-minute DEM, except that the longitudinal cell limits vary from 10 minutes at the southernmost latitude of Alaska to 18 minutes at the northernmost latitude limits of Alaska.
Densitometer	Optical device for measuring the density of photographic transparencies.
Density, of images	Measure of the opacity, or darkness, of a negative or positive transparency.
Density, of materials (ρ)	Ratio of mass to volume of a material, typically expressed as grams per cubic centimeter.

Density slicing	Process of converting the continuous gray tones of an image into a series of density intervals, or slices, each corresponding to a specific digital range. The density slices are then displayed either as uniform gray tones or as colors.
Depolarized	Refers to a change in polarization of a transmitted radar pulse as a result of various interactions with the terrain surface.
Depression angle (y)	In radar, the angle between the imaginary horizontal plane passing through the antenna and the line connecting the antenna and the target.
Descending Node	Direction satellite is traveling relative to the Equator. A descending node would imply a southbound Equatorial crossing.
Detectability	Measure of the smallest object that can be discerned on an image.
Detector	Component of a remote sensing system that converts electromagnetic radiation into a recorded signal.
Developing	Chemical processing of an exposed photographic emulsion to produce an image.
Dielectric constant	Electrical property of matter that influences radar returns. Also referred to as complex dielectric constant.
Difference image	Image prepared by subtracting the digital values of pixels in one image from those in a second image to produce a third set of pixels. This third set is used to form the difference image.
Diffuse reflector	Surface that reflects incident radiation nearly equally in all directions.
Digital display	A form of data display in which values are shown as arrays of numbers.
Digital image	An image where the property being measured has been converted from a continuous range of analogue values to a range expressed by a finite number of integers, usually recorded as binary codes from 0 to 255, or as one byte.
Digital image processing	Computer manipulation of the digital-number values of an image.
Digital number (DN)	Value assigned to a pixel in a digital image.
Digitization	Process of converting an analog display into a digital display.
Digitizer	Device for scanning an image and converting it into numerical format.
Directional filter	Mathematical filter designed to enhance on an image those linear features oriented in a particular direction.
Distortion	On an image, changes in shape and position of objects with respect to their true shape and position.
Diurnal	Daily.
DLG--Digital Line Graph	A DLG is line map information in digital form. The DLG data files include information about planimetric base categories, such as transportation, hydrography, and boundaries.
DMA--Defense Mapping Agency	The DMA was established in 1972, when mapping, charting, and geodesy functions of the Defense Community were combined into this joint Department of Defense agency. The mission of the Agency is to: produce and distribute to the Joint Chiefs of Staff, unified and specified commands, military departments, and other department of defense users, timely and uniquely tailored mapping, charting, and geodetic products, services, and training; provide nautical charts and marine navigational data to worldwide merchant marine and private vessel operators; and maintain liaison with civil agencies and other national and international scientific and other organizations engaged in mapping, charting, and geodetic activities. The above activities were handled by the DMA Combat Support Center until the Center was disbanded in 1995 and responsibilities were transferred to the National Imagery Mapping Agency (NIMA)
Doppler principle	Describes the change in observed frequency that electromagnetic or other waves undergo as a result of the movement of the source of waves relative to the observer.

Doppler radar	The weather radar system that uses the Doppler shift of radio waves to detect air motion that can result in tornadoes and precipitation, as previously-developed weather radar systems do. It can also measure the speed and direction of rain and ice, as well as detect the formation of tornadoes sooner than older radars.
Doppler shift	A change in the observed frequency of EM or other waves caused by the relative motion between source and detector. Used principally in the generation of synthetic-aperture radar images.
DOQQ	Digital ortho-quarter quadrangle
Drainage Basin	Geographic area or region containing one or more drainage areas that discharge run-off to a single point.
DTM--Digital Terrain Model	A DTM is a land surface represented in digital form by an elevation grid or lists of three-dimensional coordinates.
Dwell time	Time required for a detector IFOV to sweep across a ground resolution cell.

E

Earth Observing System (EOS)	A series of small- to intermediate-sized spacecraft that is the centerpiece of NASA's Mission to Planet Earth (MTPE). Planned for launch beginning in 1998, each of each of the EOS spacecraft will carry a suite of instruments designed to study global climate change. MTPE will use space-, aircraft-, and ground-based measurements to study our environment as an integrated system. Designing and implementing the MTPE is, of necessity, an international effort. The MTPE program involves the cooperation of the U.S., the European Space Agency (ESA), and the Japanese National Space Development Agency (NASDA). The MTPE program is part of the U.S. interagency effort, the Global Change Research Program.
EDAC--Earth Data Analysis Center	EDAC, also known as the Technology Applications Center (TAC), has served as a NASA center since 1964. EDAC operates under the objective of transferring Earth-observing technologies to the user community. It supports and works directly with industries developing technologies related to space science and collaborating with them to enhance and encourage the user community to adopt the new technologies. EDAC also supports and works with public agencies, private citizens, educational organizations, and volunteer groups to ensure ready accessibility to NASA generated space imagery.
EDC	EROS Data Center.
Edge	A boundary in an image between areas with different tones.
Edge enhancement	Image-processing technique that emphasizes the appearance of edges and lines.
Ektachrome	A Kodak color positive film.
Electromagnetic radiation	Energy propagated in the form of and advancing interaction between electric and magnetic fields. All electromagnetic radiation moves at the speed of light.
Electromagnetic spectrum	Continuous sequence of electromagnetic energy arranged according to wavelength or frequency.

El Niño	A warming of the surface waters of the eastern equatorial Pacific that occurs at irregular intervals of 2-7 years, lasting 1-2 years. Along the west coast of South America, southerly winds promote the upwelling of cold, nutrient-rich water that sustains large fish populations that sustain abundant sea birds, whose droppings support the fertilizer industry. Near the end of each calendar year, a warm current of nutrient-pool tropical water replaces the cold, nutrient-rich surface water. Because this condition often occurs around Christmas, it was named El Niño (Spanish for boy child, referring to the Christ child). In most years the warming last only a few weeks or a month, after which the weather patterns return to normal and fishing improves. However, when El Niño conditions last for many months, more extensive ocean warming occurs and economic results can be disastrous. El Niño has been linked to wetter, colder winters in the United States; drier, hotter summers in South America and Europe; and drought in Africa. See ENSO.
Emission	Process by which a body radiates electromagnetic energy. Emission is determined by kinetic temperature and emissivity.
Emissivity (e)	Ratio of radiant flux from a body to that from a blackbody at the same kinetic temperature and emissivity.
Emittance	A term for the radiant flux of energy per unit area emitted by a body. (Now obsolete).
Emulsion	Suspension of photosensitive silver halide grains in gelatin that constitutes the image-forming layer on photographic film.
Energy flux	Radiant flux.
Enhancement	Process of altering the appearance of an image so that the interpreter can extract more information.
ENSO (El Niño-Southern Oscillation)	Interacting parts of a single global system of climate fluctuations. ENSO is the most prominent known source of interannual variability in weather and climate around the world, though not all areas are affected. The Southern Oscillation (SO) is a global-scale seesaw in atmospheric pressure between Indonesia/North Australia, and the southeast Pacific. In major warm events El Niño warming extends over much of the tropical Pacific and becomes clearly linked to the SO pattern. Many of the countries most affected by ENSO events are developing countries with economies that are largely dependent upon their agricultural and fishery sectors as a major source of food supply, employment, and foreign exchange. New capabilities to predict the onset of ENSO event can have a global impact. While ENSO is a natural part of the Earth's climate, whether its intensity or frequency may change as a result of global warming is an important concern.
EOSAT	The commercial company that took over operations of the Landsat system in 1985.
Ephemeris	A table of predicted satellite orbital locations for specific time intervals. The ephemeris data help to characterize the conditions under which remotely sensed data are collected and are commonly used to correct the sensor data prior to analysis.
ERBSS	Earth Radiation Budget Sensor System, carried by NOAA satellites.
EREP	Earth Resources Experiment Package, carried on Skylab and consisting of cameras and multispectral scanner.
EROS	Earth Resources Observation System.
EROS Data Center (EDC)	Facility of the U.S. Geological Survey at Sioux Falls, South Dakota, that archives, processes, and distributes images.
ERTS	Earth Resource Technology Satellite, now called Landsat.
ESA	European Space Agency, based in Paris. A consortium between several European states for the development of space science, including the launch of remote-sensing satellites.

ETC	Earth-terrain camera.
Evaporative cooling	Temperature drop caused by evaporation of water from a moist surface.
Exitance	The radiant flux.
F	
False color image	A color image where parts of the non-visible EM spectrum are expressed as one or more of the red, green, and blue components, so that the colors produced by the Earth's surface do not correspond to normal visual experience. Also called a false-color composite (FCC). The most commonly seen false-color images display the very-near infrared as red, red as green, and green as blue.
False color photograph	Another term for IR color photograph.
Far range	The portion of a radar image farthest from the aircraft or spacecraft flight path.
Fiducial Marks	A set of four marks located in the corners or edge-centered, or both, of a photographic image. These marks are exposed within the camera onto the original film and are used to define the frame of reference for spatial measurements on aerial photographs. Opposite fiducial marks connected, intersect at approximately the image center of the aerial photograph.
Film	Light-sensitive photographic emulsion and its base.
Film speed	Measure of the sensitivity of photographic film to light. Larger numbers indicate higher sensitivity.
Film Types	Photographic products for use in image interpretation are commonly generated from the following film types: • Black-and-White Panchromatic (B&W): This film primarily consists of a black-and-white negative material with a sensitivity range comparable to that of the human eye. It has good contrast and resolution with low graininess and a wide exposure range. • Black-and-White Infrared (BIR): With some exceptions, this film is sensitive to the spectral region encompassing 0.4 <u>micrometers</u> to 0.9 micrometers. It is sometimes referred to as near-infrared film because it utilizes only a narrow portion of the total infrared spectrum (0.7 micrometers to 0.9 micrometers). • Conventional Color: This film contains three emulsion layers that are sensitive to blue, green, and red (the three primary colors of the visible spectrum). This film replicates colors as seen by the human eye and is commonly referred to as normal or natural color. Color film is a valuable image interpretation tool because the human eye can discern a greater variety of color tones than gray tones. • Color Infrared (CIR): This film, originally referred to as camouflage-detection film because of its warfare applications, differs from conventional color film because its emulsion layers are sensitive to green, red, and near-infrared radiation (0.5 micrometers to 0.9 micrometers). Used with a yellow filter to absorb the blue light, this film provides sharp images and penetrates haze at high altitudes. Color-infrared film also is referred to as false-color film.
	Mathematical procedure for modifying values of numerical data.
Filter, optical	A material that, by absorption or reflection, selectivity modifies the radiation transmitted through an optical system.

Flight path	Line on the ground directly beneath a remote sensing aircraft or spacecraft. Also called flight line.
Fluorescence	Emission of light from a substance following exposure to radiation from an external source.
F-number	Representation of the speed of a lens determined by the focal length divided by diameter of the lens. Smaller numbers indicate faster lenses.
Focal length	In cameras, the distance from the optical center of the lens to the plane at which the image of a very distant object is brought into focus.
Foreshortening	A distortion in radar images causing the lengths of slopes facing the antenna to appear shorter on the image than on the ground. It is produced when radar wave fronts are steeper than the topographic slope.
Format	Size of an image
Forward overlap	The percent of duplication by successive photographs along a flight line.
Fovea	The region around that point on the retina intersected by the eye's optic axis, where receptors are most densely packed. It is the most sensitive part of the retina.
Frequency (v)	The number of wave oscillations per unit time or the number of wavelengths that pass a point per unit time.
F-stop	Focal length of a lens divided by the diameter of the lens's adjustable diaphragm. Smaller numbers indicate larger openings, which admit more light to the film.
G	
GAC--Global Area Coverage	GAC data are derived from a sample averaging of the full resolution AVHRR data. Four out of every five samples along the scan line are used to compute one average value and the data from only every third scan line are processed, yielding 1.1 km by 4 km resolution at the subpoint.
Gamma	This is a unit of magnetic intensity.
GCP	Ground-control point. GCPs are physical points on the ground whose positions are known with respect to some horizontal coordinate system and/or vertical datum. When mutually identifiable on the ground and on a map or photographic image, ground control points can be used to establish the exact spatial position and orientation of the image to the ground. Ground control points may be horizontal control points, vertical control points, or both.
Gemini	U.S. program of two-man earth-orbiting spacecraft in 1965 and 1966.
Geodetic	Of or determined by geodesy; that part of applied mathematics which deals with the determination of the magnitude and figure either of the whole Earth or of a large portion of its surface. Also refers to the exact location points on the Earth's surface.
Geodetic accuracy	The accuracy with which geographic position and elevation of features on the Earth's surface are mapped. This accuracy incorporates information in which the size and shape of the Earth has been taken into account.
Geographic information system (GIS)	A data-handling and analysis system based on sets of data distributed spatially in two dimensions. The data sets may be map oriented, when they comprise qualitative attributes of an area recorded as lines, points, and areas often in vector format, or image oriented, when the data are quantitative attributes referring to cells in a rectangular grid usually in raster format. It is also known as a geobased or geocoded information system.
Geometric correction	Image-processing procedure that corrects spatial distortions in an image.

Georegistered	An image that has been geographically referenced or rectified to an Earth model, usually to a map projection. Sometimes referred to as geocoded or geometric registration.
Geostationary	Refers to satellites traveling at the angular velocity at which the earth rotates; as a result, they remain above the same point on earth at all times.
Geostationary Operational Environmental Satellite (GOES)	a NOAA satellite that acquires visible and thermal IR images for meteorological purposes such as: • Provide continuous day and night weather observations; • Monitor severe weather events such as hurricanes, thunderstorms, and flash floods; • Relay environmental data from surface collection platforms to a processing center; • Perform facsimile transmissions of processed weather data to low-cost receiving stations; • Monitor the Earth's magnetic field, the energetic particle flux in the satellite's vicinity, and x-ray emissions from the sun; • Detect distress signals from downed aircraft and ships. points 35,790 km (22,240 miles) above the equator at 75 degrees west and 135 degrees west. GOES satellites have an equatorial, Earth-synchronous orbit with a 24-hour period, a visible resolution of 1 km, an IR resolution of 4 km, and a scan rate of 1864 statute miles in three minutes. See geostationary. The transmission of processed weather data (both visible and infrared) by GOES is called weather facsimile (WEFAX). GOES WEFAX transmits at 1691+ mhz and is accessible via a ground station with a satellite dish antenna. GOES carries the following five major sensor systems: 1. The imager is a multispectral instrument capable of sweeping simultaneously one visible and four infrared channels in a north-to-south swath across an east-to-west path, providing full disk imagery once every thirty minutes. 2. The sounder has more spectral bands than the imager for producing high quality atmospheric profiles of temperature and moisture. It is capable of stepping one visible and eighteen infrared channels in a north-to-south swath across an east-to-west path. 3. The Space Environment Monitor (SEM) measures the condition of the Earth's magnetic field, the solar activity and radiation around the spacecraft, and transmits these data to a central processing facility. 4. The Data Collection System (DCS) receives transmitted meteorological data from remotely located platforms and relays the data to the end-users. 5. The Search and Rescue Transponder can relay distress signals at all times, but cannot locate them. While only the polar-orbiting satellite can locate distress signals, the two types of satellites work together to create a comprehensive search and rescue system.
Geostationary orbit	An orbit at 41 000 km in the direction of the Earth's rotation, which matches speed so that a satellite remains over a fixed point on the Earth's surface.
Geosynchronous (aka GEO)	geostationary.

Geothermal	Refers to heat from sources within the earth.
Goddard Space Flight Center (GSFC)	The NASA facility at Greenbelt, Maryland, that is also a Landsat ground receiving station.
GMT	Greenwich mean time. This international 24-h system is used to designate the time at which Landsat images are acquired.
GOES	
Gossan	Surface occurrence of iron oxide formed by the weathering of metallic sulfide ore minerals.
GPS--Global Positioning System	The GPS is a worldwide satellite navigation system that is funded and supervised by the U.S. Department of Defense. GPS satellites transmit specially coded signals. These signals are processed by a GPS receiver that computes extremely accurate measurements, including 3-dimensional position, velocity, and time on a continuous basis
Granularity	Graininess of developed photographic film that is determined by the texture of the silver grains.
GRASS--Geographic Resources Analysis Support System	GRASS is a product of the U.S. Army Corps of Engineers Construction Engineering Research Laboratories (USACERL) in Champaign, Illinois. It is an integrated set of programs designed to provide digitizing, image processing, map production, and geographic information system capabilities to its users.
Gray scale	A sequence of gray tones ranging from black to white.
Grid format	irregularly distributed points, or along survey lines, to values referring to square cells in a rectangular array. It forms a step in the process of contouring data, but can also be used as the basis for a raster format to be displayed and analyzed digitally after the values have been rescaled to the 0-255 range.
Ground-control point	A geographic feature of known location that is recognizable on images and can be used to determine geometric corrections.
Ground range	On radar images, the distance from the ground track to an object.
Ground-range image	Radar image in which the scale in the range direction is constant.
Ground receiving station	
Ground resolution cell	Area on the terrain that is covered by the IFOV of a detector.
Ground swath	Width of the strip of terrain that is imaged by a scanner system.
GSFC	Goddard Space Flight Center
H	
	Refers to waves in which the component frequencies are whole-number multiples of the fundamental frequency.
HCMM	Heat Capacity Mapping Mission, the NASA satellite launched in 1978 to observe thermal properties of rocks and soils. It remained in orbit for only a few months.
Heat capacity-(c)	temperature rise or fall. Expressed in calories per gram per degree centigrade. Also called thermal capacity.
Heat Capacity Mapping Mission (HCMM)	NASA satellite orbited in 1978 to record daytime and nighttime visible and thermal IR images of large areas.
Highlights	
High-pass filter	A spatial filter that selectively enhances contrast variations with high spatial frequencies in an image. It improves the sharpness of images and is a method of edge enhancement.
HIRIS-High Resolution Imaging Spectrometer	Possibly to be carried by the Space Shuttle.
HIRS-High Resolution Infrared Spectrometer	Carried by NOAA satellites.

Histogram	A means of expressing the frequency of occurrence of values in a data set within a series of equal ranges or bins, the height of each bin representing the frequency at which values in the data set fall within the chosen range. A cumulative histogram expresses the frequency of all values falling within a bin and lower in the range. A smooth curve derived mathematically from a histogram is termed the probability density function (PDF).
HORIZONTAL POLARIZATION	Transmission of microwaves so that the electric lines of force are horizontal, while the magnetic lines of force are vertical.
HRPT--High Resolution Picture Transmission	HRPT data are full resolution image data transmitted to a ground station as they are collected. The average instantaneous field-of-view of 1.4 milliradians yields a HRPT ground resolution of approximately 1.1 km at the satellite nadir from the nominal orbit altitude of 833 km (517 mi).
HRV--High Resolution Visible Imaging Instrument	The HRV instrument is a multispectral radiometer designed for SPOT spacecraft. The HRV instrument provides for high-resolution imaging in the visible and near-infrared portions of the electromagnetic spectrum. The first three SPOT satellites carry twin HRVs that operate in a number of viewing configurations and in different spectral modes. Some of those viewing configurations and spectral modes include one HRV only operating in a dual spectral mode (i.e., in both panchromatic mode and multispectral mode); two HRVs operating in the twin-viewing configuration (i.e., one HRV in panchromatic mode and one HRV in multispectral mode); and two HRVs operating independently of each other (i.e., not in twin-viewing configuration).
Hue	In the IHS system, represents the dominant wavelength of a color.
HYDROLOGY	Scientific study of the waters of the Earth, especially with relation to the effects of precipitation and evaporation upon the occurrence and character of ground water.
HYPSOGRAPHY	level, especially the measurement and mapping of land elevation.
I	
IFOV	Instantaneous field of view.
IHS	Intensity, hue, and saturation system of colors.
Image	Pictorial representation of a scene recorded by a remote sensing system. Although image is a general term, it is commonly restricted to representations acquired by non-photographic methods.
Image dissection	The breaking down of a continuous scene into discrete spatial elements, either by the receptors on the retina, or in the process of capturing the image artificially.
Image striping	A defect produced in line scanner and push-broom imaging devices produced by the non-uniform response of a single detector, or amongst a bank of detectors. In a line-scan image the stripes are perpendicular to flight direction, but parallel to it in a push-broom image.
Image swath	See ground swath.
Incidence angle	In radar, the angle formed between an imaginary line normal to the surface and another connecting the antenna and the target.
Incident energy	Electromagnetic radiation impinging on a surface.

Index of refraction (n)	Ratio of the wavelength or velocity of electromagnetic radiation in a vacuum to that in a substance.
Instantaneous field of view (IV or IFOV)	Solid angle through which a detector is sensitive to radiation. In a scanning system, the solid angle subtended by the detector when the scanning motion is stopped.
Intensity	In the IHS system, brightness ranging from black to white.
Interactive processing	results and can alter the instructions to the computer to achieve desired results.
Interpretation	The process in which a person extracts information from an image.
Interpretation key	interpreter to identify an object on an image.
IR	Infrared region of the electromagnetic spectrum that includes wavelengths from 0.7 μ m to 1 mm.
IR color photograph	Color photograph in which the red-imaging layer is sensitive to photographic IR wavelengths, the green-imaging layer is sensitive to red light, and the blue-imaging layer is sensitive to green light. Also known as camouflage detection photographs and false-color photographs.
ISO index	Index of the International Standards Organization, designating film speed in photography. Higher values indicate higher sensitivity.
Isotherm	Contour line connecting points of equal temperature. Isotherm maps are used to portray surface-temperature patterns of water bodies.

J

Japanese National Space Development Agency (NASDA)	The agency reports to the Japanese Ministry of Science and Technology.
JNC--Jet Navigation Chart	The JNC series provides worldwide coverage at a scale of 1:2,000,000. The information on these charts are suitable for aeronautical long-range, high-altitude, high-speed travel; map features include cities, roads, railroads, lakes, principal drainage, and permanent snow/ice areas. The polar regions are in a Transverse Mercator projection. All other regions are presented in the Lambert Conformal Conic projection.
Johnson Space Flight Center	A NASA facility in Houston, Texas.
JPL	Jet Propulsion Laboratory, a NASA facility at Pasadena, California, operated under contract by the California Institute of Technology.

K

Ka band	Radar wavelength region from 0.8 to 1.1 cm.
Kelvin Units	A Kelvin Unit refers to a thermometric scale in which the degree intervals are equal to those of the Celsius scale and in which zero (0) degrees equals -273.15 degrees Celsius (absolute zero)
Kernel	Two-dimensional array of digital numbers used in digital filtering.
Kinetic energy	The ability of a moving body to do work by virtue of its motion. The molecular motion of matter is a form of kinetic energy.
Kinetic temperature	Internal temperature of an object determined by random molecular motion. Kinetic temperature is measured with a contact thermometer.
Kodachrome	A Kodak color positive film.

L

LAC--Local Area	LAC are full resolution data recorded on an onboard tape recorder for
-----------------	---

Coverage	subsequent transmission during a station overpass. The average instantaneous field-of-view of 1.4 milliradians yields a LAC ground resolution of approximately 1.1 km at the satellite nadir from the nominal orbit altitude of 833 km.
LACIE	Large Area Crop Inventory Experiment
Lambert Azimuthal Equal Area Projection	Azimuthal projections are formed onto a plane, which is usually tangent to the globe at either pole, the Equator, or any intermediate point. The Lambert Azimuthal Equal Area projection is a method of projecting maps on which the azimuth or direction from a given central point to any other point is shown correctly and also on which the areas of all regions are shown in the same proportion of their true areas. When a pole is the central point, all meridians are spaced at their true angles and are straight radii of concentric circles that represent the parallels. This projection is frequently used in one of three aspects: The polar aspect is used in atlases for maps of polar regions and of the Northern and Southern Hemispheres; the equatorial aspect is commonly used for atlas maps of the Eastern and Western Hemispheres; and the oblique aspect is used for atlas maps of continents and oceans.
Lambert Conformal Conic Projection	The Lambert Conformal Conic Projection is derived by the projection of lines from the center of the globe onto a simple cone. This cone intersects the Earth along two standard parallels of latitude, both of which are on the same side of the equator. All meridians are converging straight lines that meet at a common point beyond the limits of the map. Parallels are concentric circles whose center is at the intersection point of the meridians. Parallels and meridians cross at right angles, an essential of conformality. chosen to enclose two-thirds of the north to south map area. Between these parallels, the scale will be too small, and beyond them, too large. If the north to south extent of the mapping is limited, maximum scale errors will rarely exceed one percent. Area exaggeration between and near the standard parallels, is very slight; thus, the projection provides good directional and shape relationships for areas having their long axes running in an east to west belt.
LANDSAT (formerly ERTS)	The Landsat program, first known as the Earth Resources Technology Satellite (ERTS) Program, is a development of the National Aeronautics and Space Administration (NASA) in association with NOAA, USGS, and the Space Imaging. The activities of these combined groups led to the concept of dedicated Earth-orbiting satellites, the defining of spectral and spatial requirements for their instruments, and the fostering of research to determine the best means of extracting and using information from the data. The first satellite, ERTS 1, was launched on 7/23/72. The second satellite was launched on 1/22/75. Concurrently the name of the satellites and program was changed to emphasize its prime area of interest (land resources). The first two satellites were designated as Landsats 1 and 2. Landsat 3 was launched on 3/5/78. Landsat 4 was launched on 7/16/82. Landsat 5 (launched 3/1/84) is currently in service providing selected data to worldwide researchers.
Laplacian filter	A form of nondirectional digital filter.
Large-format camera (LFC)	An experiment first carried on the Space Shuttle in October 1984.
Laser	Light artificially stimulated electromagnetic radiation: a beam of coherent radiation with a single wavelength.
Latitude (aka the geodetic latitude)	The angle between a perpendicular at a location, and the equatorial plane of the Earth.

Latent image	Invisible image produced by the photochemical effect of light on silver halide grains in the emulsion of film. The latent image is not visible until after photographic development.
Layover	In radar images, the geometric displacement of the objects toward the near range relative to their base.
L band	
Lens	One or more pieces of glass or other transparent material shaped to form an image by refraction of light.
LEVEL 1b	discrete data sets and to which Earth location and calibration information have been appended, but not applied.
LFC	Large-format camera. The LFC was a high altitude aerial mapping camera scaled up to operate from the Space Shuttle in Earth-orbital altitudes. LFC specifications included: • Film Format Size: 9 x 18 inches (23 x 46 cm) • Lens Aperture: F/6.0 -Lens Focal Length: 12 inches (30.5 cm) • Exposure Interval: 7.5 sec. • Exposure Range: 1/250 to 1/31.25 seconds • Ground Resolution: 20 meters at 160 nautical miles • Ground Coverage: 120 x 240 nautical miles at 160 nm
	Light intensity detection and ranging, which uses lasers to stimulate fluorescence in various compounds and to measure distances to reflecting surfaces.
Light	Electromagnetic radiation ranging from 0.4 to 0.7 μ m in wavelength that is detectable by the human eye.
Light meter	Device for measuring the intensity of visible radiation and determining the appropriate exposure of photographic film in a camera.
Lineament	Linear topographic or tonal feature on the terrain and on images, maps, and photographs that may represent a zone of structural weakness.
Linear	Adjective that describes the straight line-like nature of features on the terrain or on images and photographs.
Lineation	The one-dimensional alignment of internal components of a rock that cannot be depicted as an individual feature on a map.
Line drop out	The loss of data from a scan line caused by malfunction of one of the detectors in a line scanner.
Line-pair	Pair of light and dark bars of equal widths. The number of such line-pairs aligned side by side that can be distinguished per unit distance expresses the resolving power of an imaging system.
Line scanner	An imaging device, which uses a mirror to sweep the ground surface normal to the flight path of the platform. An image is built up as a strip comprising lines of data.
Look angle	The angle between the vertical plane containing a radar antenna and the direction of radar propagation. Complementary to the depression angle.
Look direction	Direction in which pulses of microwave energy are transmitted by a radar system. The look direction is normal to the azimuth direction. Also called range direction.
Look-up table (LUT)	A mathematical formula used to convert one distribution of data to another, most conveniently remembered as a conversion graph.
Longitude	The angular distance from the Greenwich meridian (0 degree), along the equator. This can be measured either east or west to the 180th meridian (180 degrees) or 0 degree to 360 degrees W.
Low-sun-angle photograph	Aerial photograph acquired in the morning, evening, or winter when the sun is at a low elevation above the horizon.

Luminance	Quantitative measure of the intensity of light from a source.
Mach band	An optical illusion of dark and light fringes within adjacent areas of contrasted tone. It is a psychophysiological phenomenon, which aids human detection of boundaries or edges.
Median filter	A spatial filter, which substitutes the median value of DN from surrounding pixels for that recorded at an individual pixel. It is useful for removing random noise.
Mercator Projection	Mercator is a conformal map projection, that is, it preserves angular relationships. Mercator was designed and is recommended for navigational use and is the standard for marine charts. Mercator is often and inappropriately used as a world map projection in atlases and for wall charts where it presents a misleading view of the world because of the excessive distortion of area in the higher latitude areas.
Mercury	U.S. program of one-man, earth-orbiting spacecraft in 1962 and 1963.
Microwave	Region of the electromagnetic spectrum in the wavelength range of 0.1 to 30 cm.
Mid-infrared (MIR)	The range of EM wavelengths from 8 to 14 μm dominated by emission of thermally generated radiation from materials; also known as thermal infrared.
Mie scattering	The scattering of EM energy by particles in the atmosphere with comparable dimensions to the wavelength involved.
Minimum ground separation	Minimum distance on the ground between two targets at which they can be resolved on an image.
Minus-blue photographs	Black-and-white photographs acquired using a filter that removes blue wavelengths to produce higher spatial resolution.
Mixed pixel	A pixel whose DN represents the average energy reflected or emitted by several types of surface present within the area that it represents on the ground; sometimes called a mixel.
Modular optoelectric multispectral scanner (MOMS)	An along-track scanner carried on the Space Shuttle that recorded two bands of data.
Modulate	To vary the frequency, phase, or amplitude of electromagnetic waves.
Modulation transfer function (MTF)	A method of describing spatial resolution.
MOMS	Modular optoelectric multispectral scanner.
MOS-1	Marine Observation Satellite, launched by Japan in 1987.
Mosaic	Composite image or photograph made by piecing together individual images or photographs covering adjacent areas.
MSS	Multispectral scanner system of Landsat that acquires images of four wavelength bands in the visible and reflected IR regions.
Multiband camera	System that simultaneously acquires photographs of the same scene at different wavelengths.
Multispectral classification	Identification of terrain categories by digital processing of data acquired by multispectral scanners.
Multispectral scanner	Scanner system that simultaneously acquires images of the same scene at different wavelengths.
N	
NAD27--North American Datum of 1927	NAD27 is defined with an initial point at Meads Ranch, Kansas, and by the parameters of the Clarke 1866 ellipsoid. The location of features on USGS topographic maps, including the definition of 7.5-minute quadrangle corners, are referenced to the NAD27.

NAD83--North American Datum of 1983	NAD83 is an Earth-centered datum and uses the Geodetic Reference System 1980 (GRS 80) ellipsoid, unlike NAD27, which is based on an initial point (Meade's Ranch, Kansas). Using recent measurements with modern geodetic, gravimetric, astrodynamic, and astronomic instruments, the GRS 80 ellipsoid has been defined as a best fit to the worldwide geoid. Because the NAD83 surface deviates from the NAD27 surface, the position of a point based on the two reference datums will be different.
Nadir	Point on the ground directly in line with the remote sensing system and the center of the earth.
NAPP--National Aerial Photography Program	NAPP was established to coordinate the collection of aerial photography covering the 48 contiguous States and Hawaii every five years. NAPP's goals are to ensure that photography with uniform scale, quality, and cloud-free coverage be made available to meet the requirements of several Federal and State agencies. The program was initiated in 1980 as the National High Altitude Photography (NHAP) program. In 1987, the program was renamed to NAPP when the flying height for the program changed from 40,000 feet to 20,000 feet. NAPP photography is available in black and white, and in most cases, color-infrared. The program is administered by the U.S. Geological Survey's National Mapping Division. NAPP imagery is used by the USGS for photo revision and land use land cover characterization work on the standard series maps at 1:24,000; 1:100,000 and 1:250,000 scales.
NASA	National Aeronautical and Space Administration.
NDVI--Normalized Difference Vegetation Index	index, i.e., the difference between Channel 2 and 1) and the sum of Channels 2 and 1. Thus $NDVI = (\text{channel } 2 - \text{channel } 1) / (\text{channel } 2 + \text{channel } 1)$.
Nearest Neighbor Resampling	When correcting image data points, the nearest neighbor technique assigns for each new pixel that pixel value which is closest in relative location to the newly computed pixel location.
Near infrared (NIR)	The shorter wavelength range of the infrared region of the EM spectrum, from 0.7 to 2.5 μm . It is often divided into very-near infrared (VNIR) covering the range accessible to photographic emulsions (0.7 to 1.0 μm), and the short-wavelength infrared (SWIR) covering the remainder of the NOR atmospheric window from 1.0 to 2.5 μm .
Near range	Refers to the portion of a radar image closest to the aircraft or satellite flight path.
Negative photograph	Photograph on film or paper in which the relationship between bright and dark tones is the reverse of that of the features on the terrain.
NESDIS--National Environmental Satellite, Data and Information Service	NESDIS is the element in NOAA that is responsible for establishing a digital archive of data collected from the current generation of NOAA operational polar orbiting satellites
NHAP	National High Altitude Photography program of the U.S. Geological Survey.
NOAA	National Oceanic and Atmospheric Administration.
Noise	Random or repetitive events that obscure or interfere with the desired information.
Nondirectional filter	Mathematical filter that treats all orientations of linear features equally.
Non-selective scattering	The scattering of EM energy by particles in the atmosphere which are much larger than the wavelengths of the energy, and which causes all wavelengths to be scattered equally.
Non-spectral hue	A hue which is not present in the spectrum of colors produced by the analysis of white light by a prism of diffraction grating. Examples are brown, magenta, and pastel shades.

Nonsystematic distortion	Geometric irregularities on images that are not constant and cannot be predicted from the characteristics of the imaging system.
Normal color film	Film in which the colors are essentially true representations of the colors of the terrain.
NSSDC	National Space Science Data Center.
O	
Oasis	A spot in a desert made fertile by water, which normally originates as groundwater.
Oblique photograph	Photograph acquired with the camera intentionally directed at some angle between horizontal and vertical orientations.
OMS	Orbital maneuvering system.
ONC--Operational Navigation Chart	The ONC series covers most of the world landmass areas at 1:1,000,000 scale. At this scale it takes 62 charts to cover the conterminous United States. Information on these charts includes cities and landmarks, drainage, and relief (shown by shading and contours). International and State boundaries are shown, but not county boundaries.
Orbit	Path of a satellite around a body such as the earth, under the influence of gravity.
Orthophotograph	A vertical aerial photograph from which the distortions due to varying elevation, tilt, and surface topography have been removed, so that it represents every object as if viewed directly from above.
Orthophotoscope	An optical-electronic device, which converts a normal vertical aerial photograph to an orthophotograph.
Ortho-correction	Correction applied to satellite imagery to account for terrain-induced distortion.
Overlap	Extent to which adjacent images or photographs cover the same terrain, expressed as a percentage.
P	
Panchromatic film	
Parallax	Displacement of the position of a target in an image caused by a shift in the observation system.
Parallax difference	between two points, which represent two locations on the ground with different elevations.
Parallel-polarized	Describes a radar pulse in which the polarization of the return is the same as that of the transmission. Parallel-polarized images may be HH (horizontal transmit, horizontal return) or VV (vertical transmit, vertical return).
Pass	In digital filters, refers to the spatial frequency of data transmitted by the filter. High-pass filters transmit high-frequency data; low-pass filters transmit low-frequency data.
Passive microwaves	Radiation in the 1 mm to 1 m range emitted naturally by all materials above absolute zero.
Passive remote sensing	terrain.
Path-and-row index	System for locating Landsat MSS and TM images.
Pattern	Regular repetition of tonal variations on an image or photograph.
Periodic line dropout	Defect on Landsat MSS or TM images in which no data are recorded for every sixth or sixteenth scan line, causing a black line on the image.

Periodic line striping	Defect on Landsat MSS or TM images in which every sixth or sixteenth scan line is brighter or darker than the others. Caused by the sensitivity of one detector being higher or lower than the others.
Photodetector	Device for measuring energy in the visible-light band.
Photogeology	Mapping and interpretation of geologic features from aerial photographs.
Photograph-	Representation of targets on film that results from the action of light on silver halide grains in the film's emulsion.
Photographic IR	Short-wavelength portion (0.7 to 0.9 μm) of the IR band that is detectable by IR color film or IR black-and-white film.
Photographic UV	Long-wavelength portion of the UV band (0.3 to 0.4 μm) that is transmitted through the atmosphere and is detectable by film.
Photomosaic	Mosaic composed of photographs.
Photon	Minimum discrete quantity of radiant energy.
Photopic vision	Vision under conditions of bright illumination.
Picture element	In a digitized image, the area on the ground represented by each digital number. Commonly contracted to pixel.
Pitch	Rotation of an aircraft about the horizontal axis normal to its longitudinal axis that causes a nose-up or nose-down attitude.
Pixel	Contraction of picture element.
Planck's Law	An expression for the variation of emittance of a blackbody at a particular temperature as a function of wavelength.
Point spread function (PSF)	The image of a point source of radiation, such as a star, collected by an imaging device. A measure of the spatial fidelity of the device.
Polarization	The direction of orientation in which the electrical field vector of electromagnetic radiation vibrates.
Polar orbit	An orbit that passes close to the poles, thereby enabling a satellite to pass over most of the surface, except the immediate vicinity of the poles themselves.
Polarized radiation	Electromagnetic radiation in which the electrical field vector is contained in a single plane, instead of having random orientation relative to the propagation vector. Most commonly refers to radar images.
Positive photograph	Photographic image in which the tones are directly proportional to the terrain brightness.
Precision	Precision is a statistical measurement of repeatability that is usually expressed as a variance or standard deviation, root mean square or <u>RMS</u>, of repeated measurements. These are expressed as x, y coordinates of arcs, label points, and tics in either single or double precision in ARC/INFO. Single-precision coordinates have up to seven significant digits of precision. This allows for a level of accuracy of approximately 10 meters for a region whose extent is 1,000,000 meters across. Double-precision coordinates have up to 15 significant digits; this allows for the precision necessary to represent any desired map accuracy at a global scale.
Previsual symptom	A vegetation anomaly that is recognizable on IR film before it is visible to the naked eye or on normal color photographs. It results when stressed vegetation loses its ability to reflect photographic IR energy and is recognizable on IR color film by a decrease in brightness of the red hues.
Primary colors	A set of three colors that in various combinations will produce the full range of colors in the visible spectrum. There are two sets of primary colors, additive and subtractive.
Principal component analysis	The analysis of covariance in a multiple data set so that the data can be projected as additive combinations on to new axes, which express different kinds of correlation among the data.

Principal-component (PC) image	Digitally processed image produced by a transformation that recognizes maximum variance in multispectral images.
Principal point	Optical center of an aerial photograph.
Printout	Display of computer data in alphanumeric format.
Probability density function (PDF)	A function indicating the relative frequency with which any measurement may be expected to occur. In remote sensing it is represented by the histogram of DN in one band for a scene.
Projection	Orderly system of lines on a plane representing a corresponding system of imaginary lines on an adopted terrestrial or celestial datum surface. Also, the mathematical concept of such a system. For maps of the Earth, a projection consists of (1) a graticule of lines representing parallels of latitude and meridians of longitude or (2) a grid.
Pulse	Short burst of electromagnetic radiation transmitted by a radar antenna.
Pulse length	Duration of a burst of energy transmitted by a radar antenna, measured in microseconds.
Pushbroom scanner	An alternate term for an along-track scanner
Pushbroom system	An imaging device consisting of a fixed linear array of many sensors, which is swept across an area by the motion of the platform, thereby building up an image. It relies on sensors whose response and reading is nearly instantaneous, so that the image swathe can be segmented into pixels representing small dimensions on the ground.
Quantum	The elementary quantity of EM energy that is transmitted by a particular wavelength. According to the quantum theory, EM radiation is emitted, transmitted, and absorbed as numbers of quanta, the energy of each quantum being a simple function of the frequency of the radiation.
R	
	Acronym for radio detection and ranging. Radar is an active form of remote sensing that operates in the microwave and radio wavelength regions.
Radar altimeter	A non-imaging device that records the time of radar returns from vertically beneath a platform to estimate the distance to and hence the elevation of the surface; carried by Seasat and the EAS-ERS-1 platforms.
Radar cross section	A measure of the intensity of backscattered radar energy from a point target. Expressed as the area of a hypothetical surface, which scatters radar equally in all directions and which would return the same energy to the antenna.
Radar scattering coefficient	A measure of the back-scattered energy from a target with a large area. Expressed as the average radar cross section per unit area in decibels (db). It is the fundamental measure of the radar properties of a surface.
Radar scatterometer	terrain as a function of depression angle.
Radar shadow	Dark signature on a radar image representing no signal return. A shadow extends in the far-range direction from an object that intercepts the radar beam.
Radial relief displacement	The tendency of vertical objects to appear to lean radially away from the center of a vertical aerial photograph. Caused by the conical field of view of the camera lens.
Radian	Angle subtended by an arc of a circle equal in length to the radius of the circle 1 rad = 57.3°.

Radiance	Measure of the energy radiated by an object. In general, radiance is a function of viewing angle and spectral wavelength and is expressed as energy per solid angle.
Radiant energy peak	Wavelength at which the maximum electromagnetic energy is radiated at a particular temperature.
Radiant flux	Rate of flow of electromagnetic radiation measured in watts per square centimeter.
Radiant temperature	Concentration of the radiant flux from a material. Radiant temperature is the kinetic temperature multiplied by the emissivity to the one-fourth power.
Radiation	Propagation of energy in the form of electromagnetic waves.
Radiometer	Device for quantitatively measuring radiant energy, especially thermal radiation.
Random line dropout	In scanner images, the loss of data from individual scan lines in a nonsystematic fashion.
Range	In radar usage this is the distance in the direction of radar propagation, usually to the side of the platform in an imaging radar system. The slant range is the direct distance from the antenna to the object, whereas the distance from the ground track of the platform to the object is termed the ground range.
Range direction	See look direction.
Range resolution	In radar images, the spatial resolution in the range direction, which is determined by the pulse length of the transmitted microwave energy.
Raster	The scanned and illuminated area of a video display, produced by a modulated beam of electrons sweeping the phosphorescent screen line by line from top to bottom at a regular rate of repetition.
Raster format	A means of representing spatial data in the form of a grid of DN, each line of which can be used to modulate the lines of a video raster.
Raster pattern	Pattern of horizontal lines swept by an electron beam across the face of a CRT that constitute the image display.
Ratio image	An image prepared by processing digital multi-spectral data as follows: for each pixel, the value for one band that is divided the value of another. The resulting digital values are displayed as an image.
Rayleigh criterion	In radar, the relationship between surface roughness, depression angle, and wavelength that determines whether a surface will respond in a rough or smooth fashion to the radar pulse.
Rayleigh scattering	Selective scattering of light in the atmosphere by particle that is small compared with the wavelength of light.
RBV	Return-beam vidicon.
Real-aperture radar	Radar system in which azimuth resolution is determined by the transmitted beam width, which is in turn determined by the physical length of the antenna and by the wavelength.
Real time	Refers to images or data made available for inspection simultaneously with their acquisition.
Recognizability	Ability to identify an object on an image.
Rectilinear	Refers to images with no geometric distortion in which the scales in the horizontal and vertical directions are identical.
Redundancy	Information on an image, which is either not, required for interpretation or cannot be seen. Redundancy may be spatial or spectral. The term also refers to multispectral data where the degree of correlation between bands is so high that one band contains virtually the same information as all the bands.
Reflectance	it. Spectral reflectance is the reflectance measured within a specific wavelength interval.

Reflected energy peak	Wavelength (0.5 μm) at which maximum amount of energy is reflected from the earth's surface.
Reflected IR	consists primarily of reflected solar radiation.
Reflectivity	Ability of a surface to reflect incident energy.
Refraction	Bending of electromagnetic rays as they pass from one medium into another when each medium has a different index of refraction.
Registration	Process of superposing two or more images or photographs so that equivalent geographic points coincide.
Relief	Vertical irregularities of a surface.
Relief displacement	Geometric distortion on vertical aerial photographs. The tops of objects appear in the photograph to be radially displaced from their bases outward from the photograph's center point.
Remote sensing	Collection and interpretation of information about an object without being in physical contact with the object.
Resampling	The calculation of new DN for pixels created during geometric correction of a digital scene, based on the values in the local area around the uncorrected pixels.
Reseau marks	
Resolution	Ability to separate closely spaced objects on an image or photograph. Resolution is commonly expressed as the most closely spaced line-pairs per unit distance that can be distinguished. Also called spatial resolution.
Resolution target	Series of regularly spaced alternating light and dark bars used to evaluate the resolution of images or photographs.
Resolving power	A measure of the ability of individual components. And of remote sensing systems, to separate closely spaced targets.
Reststrahlen band	In the IR region, refers to absorption of energy as a function of silica content.
Return	In radar, a pulse of microwave energy reflected by the terrain and received at the radar antenna. The strength of a return is referred to as return intensity.
Return-beam vidicon (RBV)	a vacuum tube; the image is scanned with an electron beam and transmitted or recorded. Landsat 3 used a pair of RBV's to acquire images.
Ringling	Fringe-like artifacts produced at edges by some forms of spatial-frequency filtering.
Rods	The receptors in the retina that are sensitive to brightness variations.
Roll	Rotation of an aircraft that causes a wing-up or wing-down attitude.
Roll compensation system	Component of an airborne scanner system that measures and records the roll of the aircraft. This information is used to correct the imagery for distortion due to roll.
Rough criterion	In radar, the relationship between surface roughness, depression angle, and wavelength that determines whether a surface will scatter the incident radar pulse in a rough or intermediate fashion.
Roughness	In radar, the average vertical relief of a small-scale irregularities of the terrain surface. Also called surface roughness
RMSE (Root Mean Square Error)	The RMSE statistic is used to describe accuracy encompassing both random and systematic errors. The square of the difference between a true test point and an interpolated test point divided by the total number of test points in the arithmetic mean. The square root of this value is the root mean square error.
S	
SAMII	Stratospheric Aerosol Measurement experiment, carried by Nimbus-7.

SAMS	Stratospheric and Mesospheric Sounder, carried by Nimbus-7.
SAST (Scientific Assessment and Strategy Team)	SAST is an interdisciplinary team of senior scientists and engineers from various Federal Government agencies assigned to assess and report on the damage caused by the flood of 1993 and to provide assistance and advice to Federal officials responsible for making decisions with respect to the flood recovery in the Upper Mississippi and Missouri River basin.
Satellite	An object in orbit around a celestial body.
Saturation	In the IHS system, represents the purity of color. Saturation is also the condition where energy flux exceeds the sensitivity range of a detector.
SBUV	Solar Back-scatter Ultraviolet Instrument, carried by NOAA satellites.
Scale	Ratio of distance on an image to the equivalent distance on the ground.
Scan line	Narrow strip on the ground that is swept by IFOV of a detector in a scanning system.
Scanner	An imaging system in which the IFOV of one or more detectors is swept across the terrain.
Scanner distortion	Geometric distortion that is characteristic of cross-track scanner images.
Scan skew	Distortion of scanner images caused by forward motion of the aircraft or satellite during the time required for scanning completion.
Scattering	Multiple reflections of electromagnetic waves by particles or surfaces.
Scattering coefficient curves	Display of scatterometer data in which relative backscatter is shown as a function of incidence angle.
Scatterometer	Nonimaging radar device that quantitatively records backscatter of terrain as a function of incidence angle.
Scene	Area on the ground that is covered by an image or photograph.
Scotopic vision	Vision under conditions of low illumination, when only the rods are sensitive to light. Visual acuity under these conditions is highest in the blue part of the spectrum.
Seasat	NASA unmanned satellite that acquired L-band radar images in 1978.
Sensitivity	Degree to which a detector responds to electromagnetic energy incident on it.
Sensor	Device that receives electromagnetic radiation and converts it into a signal that can be recorded and displayed as either numerical data or an image.
Shaded relief	Shading added to an image that makes the image appear to have three-dimensional aspects. This type of enhancement is commonly done to satellite images and thematic maps utilizing digital topographic data to provide the appearance of terrain relief within the image.
Shuttle imaging radar (SIR)	L-band radar system deployed on the Space Shuttle.
Sidelap	Extent of lateral overlap between images acquired on adjacent flight lines.
Side-looking airborne radar (SLAR)	An airborne side scanning system for acquiring radar images.
Side-scanning sonar-	Active system for acquiring images of the seafloor using pulsed sound waves.
Side-scanning system-	or orbit path but offset to one side.
Signal	Information recorded by a remote sensing system.
Signal to noise ratio (S/N)	The ratio of the level of the signal carrying real information to that carrying spurious information as a result of defects in the system.
Silver halide	Silver salts that are especially sensitive to visible light and convert to metallic silver when developed.
SIR	Shuttle Imaging Radar, synthetic-aperture radar experiments carried aboard the NASA Space Shuttle in 1981 and 1984.

Skylab	U.S. Earth-orbiting workshop that housed three crews of three astronauts in 1973 and 1974.
Skylight	Component of light that is strongly scattered by the atmosphere and consists predominantly of shorter wavelengths.
Slant range	In radar, an imaginary line running between the antenna and the target.
Slant-range distance	Distance measured along the slant range.
Slant-range distortion	Geometric distortion of a slant-range image.
Slant-range image	In radar, an image in which objects are located at positions corresponding to their slant-range distances from the aircraft path. On slant-range images, the scale in the range direction is compressed in the near-range region
SLAR	Side-looking airborne radar.
SMIRR	Shuttle Multispectral Infrared Radiometer, a non-imaging spectroradiometer carried by the NASA Space Shuttle covering ten narrow wavebands in the 0.5-2.4 m range.
SMMR	Scanning Multichannel Microwave Radiometer, carried by Nimbus-7.
Smooth criterion	In radar, the relationship between surface roughness, depression angle, and wavelength that determines whether a surface will scatter the incident radar pulse in a smooth or intermediate fashion.
Software	Programs that control computer operations.
Sonar	Acronym for sound navigation ranging. Sonar is an active form of remote sensing that employs sonic energy to image the seafloor.
Space Shuttle	U.S. manned satellite program in the 1980s, officially called the Space Transportation System (STS).
Space Station	A planned series of three polar-orbiting, sun-synchronous satellites to be launched by NASA, the European Space Agency, and the Japanese Space Agency in the 1990s. They will carry a large range of remote-sensing devices.
Spatial-frequency filtering	The analysis of the spatial variations in DN of an image and the separation or suppression of selected frequency ranges.
Specific heat	The ratio of the heat capacity of unit mass of a material to the heat capacity of unit mass of water.
Spectral hue	A hue that is present in the spectral range of white light and is analyzed by a prism or diffraction grating.
Spectral reflectance	Reflectance of electromagnetic energy at specified wavelength intervals.
Spectral sensitivity	Response, or sensitivity, of a film or detector to radiation in different spectral regions.
Spectral vegetation index	An index of relative amount and vigor of vegetation. The index is calculated from two spectral bands of AVHRR imagery.
Spectrometer	Device for measuring intensity of radiation absorbed or reflected by a material as a function of wavelength.
Spectroradiometer	A device that measures the energy reflected or radiated by materials in narrow EM wavebands.
Spectrum	Continuous sequence of electromagnetic energy arranged according to wavelength or frequency.
Specular	Refers to a surface that is smooth with respect to the wavelength of incident energy.
SPOT	Système Probatoire d'Observation de la Terre. Unmanned French remote sensing satellite orbiting in the late 1980s.
Stefan-Boltzmann constant	$5.68 \times 10^{-12} \text{ W} \cdot \text{cm}^{-2} \cdot \text{K}^{-4}$.
Stefan-Boltzmann law	States that radiant flux of a blackbody is equal to the temperature to the fourth power times the Stefan-Boltzmann constant.
Stereo base	Distance between a pair of correlative points on a stereo pair that are oriented for stereo viewing.

Stereo model	Three-dimensional visual impression produced by viewing a pair of overlapping images through a stereoscope.
Stereo pair	Two overlapping images or photographs that may be viewed stereoscopically.
Stereopsis	The ability for objects to be perceived in three dimensions as a result of the parallax differences produced by the eye base.
Stereoscope	Binocular optical device for viewing overlapping images or diagrams. The left eye sees only the left image, and the right eye sees only the right image.
SSU	Stratosphere Sounding Unit, carried by NOAA-series satellites.
Subscene	A portion of an image that is used for detailed analysis.
Subtractive primary colors	Yellow, magenta, and cyan. When used as filters for white light, these colors remove blue, green and red light, respectively.
Sunglint	Bright reflectance of sunlight caused by ripples on water.
Sun-synchronous	Earth satellite orbit in which the orbit plane is nearly polar and the altitude is such that the satellite passes over all places on earth having the same latitude twice daily at the same local sun time.
Sun-synchronous orbit	A polar orbit where the satellite always crosses the Equator at the same local solar time.
Supervised classification	Digital-information extraction technique in which the operator provides training-site information that the computer uses to assign pixels to categories.
Surface phenomenon	Interaction between electromagnetic radiation and the surface of a material.
Surface roughness	See roughness.
Synthetic-aperture radar (SAR)	Radar system in which high azimuth resolution is achieved by storing and processing data on the Doppler shift of multiple return pulses in such a way as to give the effect of a much longer antenna.
Synthetic stereo images	Stereo images constructed through digital processing of a single image. Topographic data are used to calculate parallax.
System	Combination of components that constitute an imaging device.
Systematic distortion	Geometric irregularities on images that are caused by known and predictable characteristics.

T

Target	Object on the terrain of specific interest in a remote sensing investigation.
TDRS	Tracking and Data Relay Satellite
Telemeter	To transmit data by radio or microwave links.
Terrain	Surface of the earth.
Texture	Frequency of change and arrangement of tones on an image.
Thematic Data	Thematic data layers in a data set are layers of information that deal with a particular theme. These layers are typically related information that logically go together. Examples of thematic data would include a data layer whose contents are roads, railways, and river navigation routes.
Thematic Mapper (TM)	A cross-track scanner deployed on Landsat that records seven bands of data from the visible through the thermal IR regions.
Thermal capacity (c)	See heat capacity.
Thermal conductivity (K)	Measure of the rate at which heat will pass through a material, expressed in calories per centimeter per second per degree Centigrade.
Thermal crossover	On a plot of radiant temperature versus time, the point at which temperature curves for two different materials intersect.
Thermal diffusivity (k)	Governs the rate at which temperature changes within a substance, expressed in centimeters squared per second.

Thermal inertia (P)	Measure of the response of a material to temperature changes, expressed in calories per square centimeter per square root of second.
Thermal IR	IR region from 3 to 14 μm that is employed in remote sensing. This spectral region spans the radiant power peak of the earth.
Thermal IR image	Image acquired by a scanner that records radiation within the thermal IR band.
Thermal IR multispectral scanner (TIMS)	Airborne scanner that acquires multispectral images within the 8-to-14mm band of the thermal IR region.
Thermal model	Mathematical expression that relates thermal and other physical properties of a material to its temperature. Models may be used to predict temperature for given properties and conditions.
Thermography	thermograms, have been used to detect tumors and monitor blood circulation.
THIR	Temperature-Humidity Infrared Radiometer, carried by Nimbus-7.
Tie-point	used in the co-registration of images.
TIMS	Thermal IR multispectral scanner.
TM	Thematic Mapper.
Tone	Each distinguishable shade of gray from white to black on an image.
Topographic inversion	Ridges appear to be valleys, and valleys appear to be ridges. The illusion is corrected by orienting the image so that the shadows trend from the margin of the image to the bottom.
Topographic reversal	A geomorphic phenomenon in which topographic lows coincide with structural highs and vice versa. Valleys are eroded on crests of anticlines to cause topographic lows, and synclines form ridge, or topographic highs.
TOVS	
Tracking and Data Relay Satellite (TDRS)	Geostationary satellite used to communicate between ground receiving stations and satellite such as Landsat.
Training area	A sample of the Earth's surface with known properties; the statistics of the imaged data within the area are used to determine decision boundaries in classification.
Trade-off	As a result of changing one factor in a remote sensing system, there are compensating changes elsewhere in the system; such a compensating change is known as a trade-off.
Training site	Area of terrain with known properties or characteristics that is used in supervised classification.
Transmissivity	Property of a material that determines the amount of energy that can pass through the material.
Transparency	Image on a transparent photographic material, normally a positive image.
Transpiration	Expulsion of water vapor and oxygen by vegetation.
Travel time	In radar, the time interval between the generation of a pulse of microwave energy and its return from the terrain.
Tristimulus color theory	A theory of color relating all hues to the combined effects of three additive primary colors corresponding to the sensitivities of the three types of cone on the retina.
U	
Unsupervised classification	pixels to categories with no instructions from the operator.

UTM--Universal Transverse Mercator Projection	UTM is a widely used map projection that employs a series of identical projections around the world in the mid-latitude areas, each spanning six degrees of longitude and oriented to a meridian. This projection is characterized by its conformality; that is, it preserves angular relationships and scale plus it easily allows a rectangular grid to be superimposed on it. Many worldwide topographic and planimetric maps at scales ranging between 1:24,000 and 1:250,000 use this projection.
UV	wavelengths from 0.01 to 0.4m.
V	
Variance	A measure of the dispersion of the actual values of a variable about its mean. It is the mean of the squares of all the deviations from the mean value of a range of data.
VAS	Atmospheric Sounder, carried by GEOS satellites
Vector	Any quantity, which has both magnitude and direction, as opposed to scalar that has only magnitude.
Vector Data	Vector data, when used in the context of spatial or map information, refers to a format where all map data is stored as points, lines, and areas rather than as an image or continuous tone picture. These vector data have location and attribute information associated with them.
Vector format	The expression of points, lines, and areas on a map by digitized Cartesian coordinates, directions, and values.
Vegetation anomaly	Deviation from the normal distribution or properties of vegetation. Vegetation anomalies may be caused by faults, trace elements in soil, or other factors.
Vertical exaggeration	In a stereo model, the extent to which the vertical scale appears larger than the horizontal scale.
Vertical Positional Accuracy	Vertical positional accuracy is based upon the use of USGS source quadrangles, which are compiled to meet National Map Accuracy Standards (NMAS). NMAS vertical accuracy requires that at least 90 percent of well defined points tested be within one half contour interval of the correct value. Comparison to the graphic source is used as control to assess digital positional accuracy.
Vidicon	An imaging device based on a sheet of transparent material whose electrical conductivity increases with the intensity of EM radiation falling on it. The variation in conductivity across the plate is measured by a sweeping electron beam and converted into a video signal. Now largely replaced by cameras employing arrays of charge-coupled devices (ccds).
Vignetting	A gradual change in overall tone of an image from the center outwards, caused by the imaging device gathering less radiation from the periphery of its field of view than from the center. Most usually associated with the radially increasing angle between a lens and the Earth's surface, and the corresponding decrease in the light-gathering capacity of the lens.
Visible radiation	Energy at wavelengths from 0.4 to 0.7mm that is detectable by the human eye.
Visual dissonance	The disturbing effect of seeing a familiar object in an unfamiliar setting or in an unexpected color.
VISSR	Visible Infrared Spin-Scan Radiometer carried by the GOES satellites.
Volume scattering	In radar, interaction between electromagnetic radiation and the interior of a material.

W	
Watt (W)	Unit of electrical power equal to rate of work done by one ampere under a potential of one volt.
Wavelength	Distance between successive wave crests or other equivalent points in a harmonic wave.
Wien's displacement law	Describes the shift of the radiant power peak to shorter wavelengths as temperature increases.
WRS--Worldwide Reference System	The WRS is a global indexing scheme designed for the Landsat program based on nominal scene centers defined by path and row coordinates.
X	
X band	Radar wavelength region from 2.4 to 3.8 cm.
Y	
Yaw	Rotation of an aircraft about its vertical axis so that the longitudinal axis deviates left or right from the flight line.
Z	
ZENITH	Zenith is the point on the celestial sphere vertically above a given position or observer.
Zephyr	A Mediterranean term for any soft, gentle breeze.

RECLAMATION

Managing Water in the West

Series Report Number D-8260-05-05

Remote Sensing Technology: Guidelines and Applications within the Bureau of Reclamation

U.S. Department of the Interior
Bureau of Reclamation

September 2005

Mission Statements

The mission of the Department of the Interior is to protect and provide access to our Nation's natural and cultural heritage and honor our trust responsibilities to Indian Tribes and our commitments to island communities.

The mission of the Bureau of Reclamation is to manage, develop, and protect water and related resources in an environmentally and economically sound manner in the interest of the American public.

Abstract

Remote sensing might be defined as looking at something without touching it. Such a broad definition could also include weather radar views of precipitation and deriving earth interior structures from earthquake waves. Traditionally remote sensing includes looking at the Earth from aerial and satellite perspectives and interpreting the imagery, the perspective followed in this document. Topics include the physics of remote sensing, data sources, image processing, and preparation of data for inclusion in a geographic information system (GIS) for further analyses. A summary of former and current Denver Office remote sensing studies is appended to show the variety of possible topics.

Part I. Overview of Technology

1. *Glossary and Abbreviations*

The field of remote sensing and geographic information systems has accumulated a great number of technical words and phrases and acronyms. These are listed at the start of this report for reference and to help in understanding the later discussion.

Absorption: the removal of energy from the radiation spectrum.

Albedo: the percentage of incident light reflected from a surface. Equivalent to Reflectance.

Anti-solar point: the location from the viewer directly opposite the sun; the potential shadow location. The point on the sphere 180 degrees from the sun.

Aspect: the azimuth towards which a sloping surface is facing.

Attitude: the orientation of a viewing platform, such as an aircraft.

Azimuth: the horizontal orientation angle, 0 degrees = North, 90 degrees = East, etc.

Backscatter: the reverse deflection of radiation roughly towards the source.

Band: pertaining to a particular range of wavelengths.

Band combination: a set of bands used for visualization or computation.

Band ratioing: the division of an imagery band by another to reduce shadowing effects and enhance differences.

BGR: blue-green-red; an order of displaying color bands; opposite of RGB order.

Blackbody: a totally absorbing body that does not reflect radiation. Note: In thermal equilibrium, a blackbody absorbs and radiates at the same rate; the radiation will just equal the absorption when thermal equilibrium is maintained. This hypothetical body consists of a sufficient number of molecules emitting and absorbing electromagnetic radiation in all parts of the electromagnetic spectrum so that all incident radiation is completely absorbed and in all wavelengths bands and in all directions, maximum possible emission is effected.

CAD: computer aided design; a set of points, lines, polygons, shapes, text often without the rigorous topological rules of vectors.

Calibration: the adjustment of numerical values to a standard reference.

CIR: color-infrared, or false-color infrared A visualization that views the green, red, and near-infrared bands as blue, green, and red, often used in vegetation studies, where healthy green vegetation appears as bright red in the display or print.

Charge coupled device: (CCD) the type of light sensing device in digital cameras.

Clustering techniques: One pass, Fuzzy C Means, Minimum Distribution Angle, Adaptive resonance, K means, ISODATA, self-organization, etc.

Color style: the digital representation of colors, as 4-, 8-, 16-, 24-, and 32-bit numbers.

Cross-track scanning: the use of an imaging instrument whose view sweeps in a direction perpendicular to the forward motion of an aircraft or satellite viewing platform.

Data Base (DB): A computer-based management system for organizing data and descriptions.

DEM: digital elevation model, sometimes DTM, digital terrain model.

Differential Global Positioning System (DGPS): a GPS system that uses a base station for correcting and refining geographic positions.

DLG: digital line graph. Standard line vector product from the USGS.

DOQ, DOQQ: digital orthophoto (quarter)quad, a quadrangle version of an orthophoto.

DRG: digital raster graphic: an image of a scanned USGS topographic map including the collar information, georeferenced to the UTM grid.

Easting: a geographic coordinate east of some reference longitude.

Electromagnetic radiation: radiation made up of oscillating electric and magnetic fields and propagated at the speed of light. Includes gamma radiation, X-rays, ultraviolet, visible, and infrared radiation and radar and radio waves.

Elevation: (1) the height, usually above sea level. (2) the vertical orientation angle, 0 degrees = horizontal and 90 degrees = vertical.

Forward Fast Fourier Transform: the mathematical transformation of imagery into sinusoidal values of varying amplitude, frequency, and phase. Often used to start the removal of periodic noise in an image.

FLIR: Forward Looking Infra-Red. A sensor system for converting thermal imagery into television imagery.

Geographic Information System (GIS): a computer-based system for collecting, storing, retrieving, transforming, displaying, and analyzing spatial data.

Geostationary satellite: a satellite placed in an orbit about 22 thousand miles above the earth's equator such that its forward motion matches the rotation of the earth and it remains at a fixed longitude.

Global Positioning System (GPS): a system by which receiver equipment electronically monitors signals from a constellation of a couple dozen satellites to accurately determine the geographic position of the receiver in terms of latitude, longitude, and altitude.

Hyperspectral: imagery having dozens to hundreds of spectral bands at fine resolution.

IFSAR: interference synthetic aperture radar; a technique for analyzing radar imagery for fine detail.

Interference mode: a technique of analyzing radar imagery to reveal slight changes in elevation over time, such as those caused by tectonic and earthquake movements.

IR: infrared.

L1A and L1B: satellite imagery processing levels. L1A is essentially raw data. L1B is calibrated.

Lambertian reflector: a theoretical surface that reflects energy equally at all angles.

LIDAR: an instrument that determines distances by timing the return reflection of a laser beam.

Linear photodiode array: an imaging device whereby a scene is focused upon a line of photodiodes on an electronic microcircuit chip.

Mask: an image overlay whose numerical values specify the region of interest in other images.

Maximum likelihood classifier: an automated scheme of classifying pixels in an image based upon color resemblance to specified reference values.

Median filter: a numerical technique whereby a cluster, of specified extent, of adjacent pixels is examined for a median numerical value which is then placed in an output image at the cluster center. This removes the effects of extreme (noise) values.

Minimum distance to means classifier: an automated scheme of classifying pixels in an image by choosing the closest color match to specified reference values.

Mixed pixel: a color blending of numerous substances within the view of a single pixel.

Monochrome: sensed and displayed as intensity in only one spectral band; black & white.

Multispectral: having at least three spectral bands but usually less than ten.

Nadir: the location straight down from the viewpoint.

NIR: near infrared. The shortest wavelengths of the infrared region, nominally 0.75 to 3 μm .

Northing: a geographic position north of some reference latitude.

NTSC: a video format used in the USA and some other countries (PAL elsewhere). The code used to describe the United States system of color telecasting.

Othophoto: an image in which positional differences caused by the camera-landscape geometry, particularly by elevation, are removed by resampling. An orthophoto is a planimetrically correct image whereby features are in their true orthographic positions

PAL: "Phase Altering Line": a video format used in Europe and elsewhere, not in USA. Gathers data at a rate of 25 rather than 30 frames per second.

Panchromatic: same as monochrome, B&W, a single-band image.

Parallelepiped classifier: an automated scheme of classifying pixels in an image by partitioning band brightnesses at particular numerical ranges.

Pixel: smallest element of an image. Stands for “picture element”.

Planck’s Constant: the constant of proportionality (h) that relates the energy of a photon (E) with the frequency of the associated wave (η). where $h = 6.626 \times 10^{-34}$ joule•second.

Polarization: the forced orientation of the electric vector of electromagnetic energy.

Principal components analysis: a mathematical transformation of imagery data from a set of bands into the same number of bands but which are mathematically independent (orthogonal) of each other. The dominant variability appears in the first band (usually scene brightness) and the least in the last band (which appears as almost entirely noise). The transformation does not indicate the spectral causes of the resultant features, just that there is a significant difference.

Projection: any mathematical transformation of the globe onto some other usually flat surface.

Radiance: the spectral energy received by a sensor.

Raster: xy matrices of adjacent picture element values.

Rayleigh scatter: the scattering of radiation by very tiny aerosols and molecules in the atmosphere.

Remote Sensing (RS): the science the gathering of information about an object, area, or phenomenon through the analysis of data acquired by a device not in contact with them.

RGB: red-green-blue; also BGR for reverse order and R, G, B separately.

Reflectance: ratio of outgoing to incoming spectral energy. Also Albedo.

Resolution: the smallest distance represented by a single pixel.. It is minimum distance between two objects that a sensor can record distinctly.

SAR: synthetic aperture radar.

Scale: the ratio of a distance on a map or image to the real distance on the ground. Usually expressed in the form 1:5000, which is interpreted as 1 cm on the image represents 5000 cm on the ground, or in whatever units are preferred.

Signal to noise ratio: the strength of real data compared to noise values.

Spectrometer: a device that measures the intensity of radiation at different wavelengths.

Specular reflector: a mirror.

Stretching: the adjustment of a brightness distribution to a different range of values.

Supervised classification: a classification system by which a human analyst determines the classification of pixels.

SWIR: short-wave infrared. (1-3 μm).

Tasseled Cap: referring to the shape of a 2-dimensional distribution of pixel values (red and near-IR) of a scene containing vegetation.

TIN: triangular irregular network, a series of triangles often used to represent a continuous surface.

TIR: thermal infrared. Electromagnetic radiation emitted from the Earth's surface by all objects having a temperature warmer than absolute zero. Wavelengths in this range of the spectrum are within the infrared region, longer than 3 nanometers.

Training: the development of an automated classification system based upon known features and objects.

Transmissivity: the ratio of transmitted energy to the incoming energy.

Triangulation: the determination of positions by means of angles to other known positions.

Unsupervised classification: various automated classification systems.

UTM: Universal Transverse Mercator, a cylindrical, conformal projection system for generating maps of the curved Earth.

UV: ultraviolet. It is part of the electromagnetic spectrum that lies at wavelengths shorter than the violet range of the visible spectrum. The ultraviolet spectrum has wavelengths between 100 and 400 nanometers (nm).

Vector: a set of points, lines, polygons, and nodes used to describe feature locations, but with rigorous topological rules.

VNIR: visible and near infrared.

Wien's Displacement Law: For a blackbody, the product of the wavelength corresponding to the maximum radiance and the thermodynamic temperature is a constant. As a result, as the temperature rises, the maximum of the radiant energy shifts toward the shorter wavelength (greater frequency and energy) end of the spectrum. $\lambda_m = A/T$ where λ_m is the wavelength of maximum spectral emittance, $A = 2898 \mu\text{m}^\circ\text{K}$, and T = temperature, $^\circ\text{K}$. Thus, the wavelength of maximum emitted radiation is inversely proportional to the absolute ($^\circ\text{K}$) temperature.

Zenith: the location straight up from the viewpoint.

2. Physics of Remote Sensing

Remote sensing (RS) can be considered to have its origins in the 1800s with photography, though it was originally confined to views from the Earth's surface towards objects in the distance. The growing availability of aerial platforms in the 1900s provided vertical views of the Earth. Such were used primarily for general mapping and for military purposes. Altitudes for RS cameras can range from hand-held close-ups to balloons and aircraft as high as in the stratosphere. The second half of the 1900s introduced space-borne platforms for viewing the Earth. Weather satellites led the way, showing the organized cloud patterns around the globe. That was followed by satellites viewing the Earth surface at increasingly fine resolutions, though coarse resolutions are still appropriate for some global mappings.

RS generally examines objects, areas, and phenomena using the electromagnetic spectrum (Fig. 1; gamma, X-rays, ultraviolet, visible, infrared, thermal IR, microwave, radio), with wavelengths ranging by many orders of magnitude.

Fig. 1. The electromagnetic spectrum wavelengths cover many orders of magnitude.

The visible part of the spectrum is relatively narrow. The energy emitted by a theoretical black body has a distribution described by Planck's Law (Fig. 2), and the location of the peak energy is described by Wien's Law. As a substance becomes hotter, it emits more energy at all wavelengths, but the increase is greater at shorter wavelengths. The integral of Planck's Law curves gives the total energy as proportional to the fourth power of the absolute (Kelvin) temperature. The energy from the sun gets diluted by the distance to the Earth.

Fig. 2. Theoretical black body radiation from the Sun surface, diluted by distance to the Earth, and approximate radiation produced at Earth temperatures.

The total solar energy intercepted by some unit area is comparable to that emitted by a black body at a temperature of roughly 300°K and seen at close range. It is the balance of the incoming solar radiation and the outgoing Earth reflection and radiation that maintains a generally constant global temperature for the Earth.

The atmospheric gases absorb electromagnetic energy at chemically specific wavelengths, some of which are labeled in the darkened regions of Fig. 3 (adapted from <http://orbit-net.nesdis.noaa.gov/arad/fpdt/tutorial/absorb.html>). There are atmospheric “windows” (light regions of graph) which permit energy passage. The absorptions by these and other greenhouse gases keep the Earth significantly warmer than it would be without an atmosphere.

Fig. 3. Atmospheric absorptions of radiation.

RS need not be restricted to the electromagnetic spectrum. Other RS measurement styles use gravity and/or magnetic fields to probe into the Earth’s surface in search of anomalies. RS can use acoustic waves, such as sonar, earthquakes, and man-made sound pulses, to reveal objects and surfaces that are inaccessible by electromagnetic devices. However, this document will focus on electromagnetic-based of RS rather than these others.

Remote sensing detectors have greatly multiplied in types and spectral abilities, initially led by the field of astronomy and astrophysics. Photographic response to light intensity is logarithmic and even non-linear on the logarithmic scale. Photographic response starts in the near-infrared (NIR) and extends through the visible wavelengths to ultraviolet (UV) and x-rays. Electronic substitutes for photography provided linearities in signals, better sensitivities, and especially data in both longer and shorter wavelengths that are not accessible to photography. Detectors increased from single elements (photocell and photodiode scanners) to linear arrays (“pushbroom” scanners) to 2D arrays (digital cameras). The electronic data are most convenient for computer processing.

RS can be passive or active. Passive RS means that the electromagnetic radiation emitted or reflected from a surface is recorded. Examples are photography, videography, electronic cameras and some microwave devices. The sun is the usual illuminator for visible and near infrared (VNIR) bands. Thermal emission provides the signal at typical earth temperatures, mostly at thermal infrared (TIR) wavelengths of roughly 10 micrometers. Fires are easily detected at the short wave infrared (SWIR) wavelengths (roughly 3 to 5 micrometers).

Active means that the RS system illuminates its target and records the returning radiation. Examples are radar, LIDAR, and fluorescence. The latter anticipates that a surface will emit radiation in a longer wavelength (lesser energy) than that of the illumination.

Technologies have allowed an increase in spectral resolution. Monochrome (panchromatic) provides imagery in shades of gray, such as black-and-white photography. Traditional color imagery is produced by three bands, usually Red, Green, Blue (RGB). Infrared color imagery is usually presented as CIR, where the sensor band sequence of NIR, red, green are displayed as RGB. Multispectral systems have 3 to several spectral bands of data. Hyperspectral systems usually have dozens to hundreds of spectral bands of fine resolution. The transition from multispectral to hyperspectral is not precisely defined.

Color

Color to our eyes is the reception of red, green, and blue bands of light energy. Our brain then interprets intermediate colors based upon the proportion of those three. Colors are not linearly related to wavelength; red (R), yellow (Y), green (G), cyan (C), and blue (B) are not equally spaced in the spectrum. Magenta (M) is not even the color of a particular wavelength. Tans and browns do not exist as particular wavelengths but are composites of the primary colors, forming a diagonal line in the spectrum, increasing from blue to red.

The composition of color varies, depending upon whether the color is created by light sources or by light-absorbing substances or surfaces (Fig. 4).

Fig. 4. Color combinations from light emitting and absorbing sources.

There are three primary colors for light sources, as provided by luminous bodies like the sun, lamps, and TV and computer screens: red, green, and blue. These combine in pairs to form yellow, cyan, and magenta. All three, of equal intensity, form white. The absence of all form black.

Dyes are examples of light absorbing substances. The three primary dye colors are yellow, cyan, and magenta. They may also be thought of as "not-blue", "not-red", and "not-green", respectively. They add in pairs to form red, green, and blue. All together make black. The absence of all makes white.

Color can also be defined as a combination (Fig. 5) of hue, intensity, and saturation (HIS). Hue defines a color on a circular scale of 0 to 360 degrees (or 0 to 255 to stay in the byte range). The six pure colors (B, M, R, Y, G, C, back to B) are at multiples of 60 degrees. Intensity indicates the brightness of the image pixel, ranging from black (0) to white (255). Saturation shows the richness of the color. A saturation of 0 produces a colorless grayscale according to the intensity value. A saturation of 255 produces a maximum of a pure color, shown in this illustration as green. The color fusion (pan sharpening) process, to be discussed elsewhere, allows a fine resolution panchromatic image to be colorized by a coarser 3-band color image. The color image is converted to HIS. The panchromatic image is substituted for the intensity. A revised color image is then calculated from the H, new I, and S.

Fig. 5. The effects of color definition by hue, intensity, and saturation.

Sample Spectra

Photographic and eventually electronic recordings of the absorption spectra of thousands of substances, chemicals, and minerals were made over the past century for industrial and research purposes. Such spectra helped identify the presence of those specific substances in unknown materials. However, most plants have similar spectra; the differences are usually in the visible colors and caused by features such as flowers and autumn leaf colors that we can also see by our own eyes. Some common minerals have generally featureless spectra in the VNIR to SWIR range. Other minerals have spectra so unique that their presence in a mixture of substances can be readily detected. Fluorescence spectra are usually unique and can be excited by gamma, x-ray, and ultraviolet

illuminations. However, atmospheric absorptions of such illuminations restrict RS to very short observational distances. The following graphs were made using measurements from an ASDI Field Spectrometer - Full Range or gathered from similar spectra published by the USGS Spectral Laboratory. Those made using sunlight usually have noise bands from water vapor near 1.4 and 1.9 micrometers.

The following graphs show the spectra (horizontal axis: wavelength, 0.35 to 2.50 micrometers; vertical axis: reflectance) of several inorganic materials. Rocks and soils usually contain significant quantities of the quartz (Fig. 6) and feldspar (Fig. 7) minerals. Most have featureless spectra. However, some narrow bands, caused by water, can be seen in special minerals like opal. The bright carbonates (Fig. 8) have some distinctive narrow bands deep into the infrared. The copper carbonates show peaks in the blue and green. Various types of oxidized iron (Fig. 9) have a distinctive wide band in the very near infrared.

Fig. 6. Reflectance spectra of varieties of quartz minerals.

Fig. 7. Reflectance spectra of varieties of feldspar minerals.

Fig. 8. Reflectance spectra of carbonate minerals.

Fig. 9. Reflectance spectra of varieties of iron oxide minerals.

Some of the micas (Fig. 10) have a very narrow band in the middle of the spectrum. Feldspars and volcanic ash weather into the clays (Fig. 11), some of which are distinctive in their band shapes and placement.

Fig. 10. Reflectance spectra of varieties of mica minerals.

Fig. 11. Reflectance spectra of varieties of clay minerals.

Weather phenomena (Fig. 12) provide some special patterns. Blue sky becomes exponential in the blue to ultraviolet as a result of molecular scattering (the sky is pink on Mars because of scattering in the carbon dioxide atmosphere; Titan with a nitrogen and methane atmosphere has a different color). Such blue scattering and particle scattering from haze greatly degrade the remote sensing signal in the blue band. It is even worse in the near ultraviolet. In photography, a haze (meaning ultraviolet) filter is used to reduce the exposure of the blue band by ultraviolet scattering. Clouds, whether of water droplets or ice crystals, have multiple banding. Freshly fallen snow has deep black bands in the infrared.

Fig.12. Reflectance spectra of weather related features.

Water (Fig. 13; note the vertical scale) strongly absorbs energy, especially in the infrared. (There is strong noise in the infrared caused by water bands in the atmosphere.) The colors in the visible and near infrared vary according to what is in or under the water.

Fig 13. Reflectance spectra of water bodies.

Computer screens are light emission devices. Phosphorescent materials (Fig. 14) and light emitting diodes are made to glow. Liquid Crystal Displays (Fig. 15) shutter the light, while electrons control intensity of a CRT display. In both cases the ultraviolet light is much stronger than the green and red in order to get a similar intensity in the blue. Notice that the two different displays have different spectra. Both are dark in the infrared.

Fig. 14. Emission spectra of CRT computer display.

Fig. 15. Emission spectra of liquid crystal computer displays.

Green plants (Fig. 16) have a minor peak in the green wavelengths because chlorophyll strongly absorbs in the red. However, healthy green plants are very bright in the infrared. That enables their detection by false color infrared imagery. The main difference for plants is in the amplitude of the spectrum. Conifers are darker than deciduous trees. Grass is brightest.

Fig. 16. Reflectance spectra of green plants.

Flower color variations (Fig. 17) are mostly in the visible wavelengths. Lichens (a combination of algae and fungus; Fig. 18), however, do not resemble green plants. Notice the wavy spectra in the infrared. The noxious wetland weed, purple loosestrife, can illustrate seasonal changes (Fig. 19). The green leaves look like most other green plants. The purple flowers have a special peak in the blue and ultraviolet, which makes them attractive to bees. Autumn makes the leaves dark red. Winter kills the foliage and makes it tan. Biocontrol insects seriously harm the health of purple loosestrife. As they chew greater percentages of the leaves there is a strong drop in brightness in the very near infrared (Fig. 20). Eventually the leaves turn a chocolate brown.

Fig. 17. Reflectance spectra of some flowers.

Fig. 18. Reflectance spectra of lichens.

Fig. 19. Reflectance spectra of Purple loosestrife parts.

Fig. 20. Reflectance spectra of damaged purple loosestrife.

The spectra illustrated above were collected at about 2000 narrow wavelength intervals. Color photography collects in three broad bands: blue-green-red for natural color and green-red-NIR for false color infrared. Most Earth-observing satellites have similar broad-band sensors which must miss the very fine detail shown in these spectra. Special instruments aboard satellites, such as MODIS and ASTER, record 36 and 14 bands with some bands being broad and others narrow. Hyperspectral instruments are mostly mounted on aircraft. Apart from the limited view of the Hyperion hyperspectral instrument, satellite attempts have failed to become operational. Such instruments may have up to about 220 bands to record the spectral range illustrated in these graphs. The AVIRIS instrument is considered the best for hyperspectral work. Hyperspectral data need special techniques to remove atmospheric absorption effects from the spectra received at the sensor. A critical look at the graphs should show that hyperspectral data are excellent for a limited number of subjects but of no special additional value for others. Hyperspectral instruments produce such large volumes of data that computational time and storage considerations become huge and expensive.

Very fine spectral resolution also allows the determination of properties at increasing optical depths within a substance. The core of a spectral absorption band shows the top surface, while the “wings” of the band penetrate to greater depths. The weather satellites can use this technology for atmospheric properties, but it probably applies to water penetration as well.

All electronic media have a “mixed pixel” problem. That is a term that indicates that within the view of a single pixel there are many different objects with different spectral signatures. For example, a 30 meter pixel where a road is at a shoreline will have the road, water, bare soil, and vegetation all contributing to the signal of that pixel. This produces interpretation challenges, especially for automatic processing of scenes by computers. Some special techniques exist in several software packages to “unmix” the spectral signatures within hyperspectral pixels if a set of “end member” reference spectra are supplied to show the program what the pure target spectra look like.

Reflections and scattering

The incoming energy has many interactions on its way to the remote sensor. Though usually from the sun, this energy can come from the moon, lasers, and radars. The incident energy striking a surface divides into three components: absorbed, transmitted, and reflected. It is normally the reflected energy that is used in remote sensing.

All remote sensors record spectral energy, radiance, that actually gets to the sensor. This is usually different from the illumination of a scene and its reflectance (Fig. 21). The illumination may be scattered into direct and indirect, such as direct sunlight and diffuse light from the blue sky or from clouds. The surface can reflect, absorb, or transmit part of the illumination energy, usually with a spectral change. Energy coming from the surface can be absorbed or supplemented by atmospheric effects, such as haze and water vapor, or fully blocked, such as by clouds. Such processes often have a wavelength dependence. Precision remote sensing needs to account for all such processes that affect what actually is seen by the sensors.

Fig. 21. Light can follow many paths on its way to the sensor.

The reflected energy may not follow traditional optical angles. An ideal specular reflector, such as a mirror, sends the energy at an angle of reflection equal to the angle of incidence. A near-perfect specular reflector, such as a wavy water surface, sends its energy at a variety of angles close to that of an ideal reflector. When a surface is mirror-like and positioned to reflect illumination into the sensor, sun glint often results, creating a bright spot (Fig. 22). Such sun glint can become a major problem in both aerial and satellite images.

The anti-solar point (at the potential shadow of the sensor on the imaged surface) and surrounding area is usually bright because of strong backscatter from most objects. Glass beads in paint provide the same effect for highway markers and signs. The illustration from the Winchester Wasteway, Washington, shows sun glint off calm water in the lower right and, opposite the nadir, a bright anti-solar spot in the upper left, where the sunshine is on sand dunes coated with volcanic ash from Mount St. Helens. Notice that the general ground is darker at the bottom of the image than at the top, creating challenges when

Fig. 22. Sun glint and anti-solar spot can appear bright.

mosaicking adjacent views and trying to match brightnesses. The solar illumination was uniform over the entire area, but the directional scattering was not uniform.

The anti-solar point is usually the brightest location in an image. Most substances preferentially reflect light back towards where it came from. Sometimes the shadow of the aerial platform (aircraft) can be seen at that location. The location at the opposite side of the image, through the image center, is sometimes the darkest location in the image. If trees are there, the camera sees not only the shaded side of the tree, but also its shadow. That same location is also the mirror position of the sun, producing a bright solar image on flat water surfaces. If the water has waves, a general sun glint is produced about the mirror position of the sun. The greater the amplitude of the waves, the greater the

lateral extent of the sun glint. Satellite views of the sun glint on ocean surfaces can estimate the amplitude of the waves for describing the state of the sea.

The ideal diffuse reflector (Lambertian) scatters the energy equally in all directions (Fig. 23). Most natural surfaces are not ideal. Instead there are energy peaks in the specular reflection direction and more so in the reverse direction to the incident energy. The latter causes brightening in a spot about the anti-solar point. In low altitude aerial photography there can be such brightening about the shadow of the aircraft. The effects of non-Lambertian surfaces appear as apparent non-uniform illumination when mosaics are made of aerial photographs.

Fig. 23. Theoretical reflections seldom occur in nature.

In general, it is good to keep an open mind about what RS can do for a project. Technologies keep improving, allowing us to sense more and more phenomena at

increasing sensitivities and spectral resolutions. The traditional types of remote sensing, aerial photography and simple satellite imagery, are now being supplemented by many other types. The challenge is to determine the most appropriate technology for the task at hand. It may be “old” technology or something exotic.

Data Types

Image data are of two basic types, analog and digital. Analog data (Fig. 24) are continuously varying, such as the voltages in a photocell or optical density in photographic film. Analog data can be in either of three dimensions: point, line, or area. A prism or diffraction grating can split light into a spectrum for analog recording.

Fig. 24. Analog image data are continuously varying.

Digital data (Fig. 25) is quantized into integers for computer processing. The smallest image unit is known as a "pixel" or point picture element. It has a brightness value associated with it. Data can be recorded as monochrome (one color), multispectral (3 to a few colors), and hyperspectral (many colors). Data can be imaged as points, lines, and areas. Two-dimensional images can be made from single point sensors by cross-track scanning with forward motion. They can be made from line data (linear photodiode array) by forward motion perpendicular to the line. Digital cameras directly make two-dimensional images by use of two-dimensional array CCD (charge coupled device) sensors.

Fig. 25. Digital image data have specific numbers for each pixel.

Digital data can be quantized into any number of bits, or binary digits. Binary images have values of 0 and 1, black and white. Four-bit images have 16 levels of gray from black to white. Eight-bit (byte) images have 256 gray levels. 16-bit images have 65,536 gray levels.

Color images come in several types. Four-bit and eight-bit images have lookup tables assigning particular colors to the various integer numbers. 16-bit images usually have 5-bit (32 gray levels) shading for each of 3 colors (R=red, G=green, B=blue). 24-bit images have 8-bit (256 gray levels) shading for the 3 colors.

Resolution and scale

Resolution can be expressed, for digital images, as the pixel size. Weather satellite images can be as coarse as several kilometers per pixel. Aerial images and the newest generation of satellite images can achieve 1 meter pixels. Close-up photography can achieve sub-millimeter resolution if necessary.

Resolution is determined by a combination of three factors. First is the sensor system itself, such as the film grain size or the size of the CCD elements in a digital camera. Second is the optical system, expressed by the focal length of the lens.

Third is the altitude of the sensor above the subject. The resolution can be estimated in advance by simple trigonometry using similar triangles (Fig. 26). For detecting element size, d ; focal length, f ; and height, h ; the pixel size, p is given by $p = h * d / f$. Similar triangles can also be used to determine the total field of view of the image.

Fig. 26. Simple triangle for determining pixel size and view width.

A variety of surface resolutions are available from today's fleet of earth-observing satellites. Fig. 27 shows actual or simulated views, progressively zooming in on Henry Lake on the southwest side of Denver. In the upper left is a view of Colorado from a geostationary weather satellite (GOES) image, shown at 5 km resolution. It has the ability to do close-ups at 1 km. Next is a view from a polar orbiting weather satellite (NOAA-AVHRR) at 1 km resolution. An Indian satellite has a 2-band wide angle view at 180 meter resolution, useful for general vegetation mapping. The red band is simulated as the third image.

Fig. 27. A series of satellite views, at different resolutions, of Henry Lake, Southwest of Denver.

The Landsat TM series has 30 meter resolution in 6 bands (B,G,R, 2 NIR, and mid-IR) and a thermal-IR band of lesser resolution. The visible bands are displayed here in natural color.

The new high resolution satellites, IKONOS and Orbview-3, have 4 meter color in 4 bands: B,G,R, NIR. QuickBird has a similar camera, but a lower orbit gives it 2.4 meter color and 0.6 meter panchromatic resolution. The two lower rightmost views of the illustration show the same view of the south end of Henry Lake as simulated 4 meter color and 1 meter panchromatic.

The target in the Henry Lake study was an infestation of the invasive noxious weed purple loosestrife. The individual plants cannot be seen with even the finest satellite resolution. There is a “mixed-pixel” problem in addition to resolution; each pixel contains contributions of many items within the view - ground, grass, water, and other plants. Aerial photography might resolve the weeds but only if an appropriate resolution is selected.

Fig. 28 shows the same scene of a vertical view of flowering purple loosestrife at a series of simulated resolutions, differing by a factor of 2. The two lower rightmost views are enlargements of the upper left portion of the main view. The last view, at 0.5 mm resolution, shows a flower cluster, leaves, a dry seed stalk from the previous year (top) and a cattail seed head (lower left), in addition to dark views of the undergrowth. An analyst needs to select a resolution at which the presence of flowering purple loosestrife can be distinguished from other things in the view. A resolution of about 10 mm/pixel seems appropriate for presence identification but does not clearly resolve what else is in view.

Satellite resolution is fixed at specified values, such as 1 meter/pixel for panchromatic imagery from IKONOS and Orbview-3. Aerial resolution can be adjusted by the height

Fig. 28. A series of views of purple loosestrife flowers at different resolutions.

(altitude) of the camera above the surface, using a variation of the equation $p = h * d / f$ associated with the triangle of Fig. 26. For digital cameras the sensor resolution, d , is fixed and usually difficult to identify in the specifications. It may have to be calculated from the size of the CCD array and the number of pixels across its view. For photographic film that is scanned, the scanning resolution (usually in dpi - dots per inch = pixels per inch) is the inverse of d . Inserting the numbers into the equation then produces a need to carefully deal with the mixture of English and metric units! $(\text{dpi}) * (\text{pixel resolution}) * (\text{focal length}) = (\text{altitude})$ becomes $(\text{pixels/inch}) * (\text{meters/pixel}) * (\text{millimeters}) = (\text{feet})$ with the obvious need for conversion factors. In review, satellite resolution is fixed, aerial resolution can be adjusted by aircraft altitude, camera (digital or photographic) resolution can be adjusted by zooming or lens switch before picture acquisition, and scanned photographic film resolution can be adjusted by the scanner resolution up to the limit of film grain size. The resulting resolution is a solution of the available adjustments.

3. Data sources

Photography

Aerial imagery usually comes from photography, videography, and scanners. Traditional aerial mapping cameras use film as 9x9 inch frames and a 6 inch lens. The flight altitude in feet is then half of the scale number; 1:5000 scale imagery is flown at 2500 feet. Sometimes 35 mm photography is appropriate. Film types can be panchromatic (B&W), natural color, and CIR (false color). Photographic style can be negative (for positive prints) or positive (for transparencies). The transparencies usually have the greater resolution and color brilliance.

Film speed is important and interacts with shutter speed and diaphragm aperture for proper exposure and depth of view. Slow speed films have fine resolution while fast speed films are coarse grained. This is true for both panchromatic and color films. Therefore, using films which promote capabilities in situations with dim illumination results in a serious drawback of poorer resolution. Diaphragm apertures have settings, known as “f-stops”, that are on a logarithmic scale of powers of the square root of 2: 1, 1.4, 2, 2.8, 4, 5.6, 8, 11, 16, 22, 32. The smaller numbers indicate wide open apertures and the larger numbers very narrow apertures. For a constant illumination, shutter speed increases by a factor of 2 must be compensated by f-stop changes to the next smaller number. The depth of field is the range of distances at which objects are in reasonable focus. As the f-stop number gets smaller, the depth of field gets narrower. Therefore, as illumination decreases and an f-stop is adjusted to compensate, the need for precise focusing becomes greater. Popular hand-held cameras rarely have such independent controls of shutter speed and f-stops. Full control of these features allow a photographer the options of having everything in focus, from nearby objects to infinity, or only a particular object in focus while things in the foreground and background are out of focus.

For aerial photography from great heights, aircraft motion has little effect. When flights are close to the ground (1:5000 or finer scales, for example) fast shutter speed or fast film speed become important. A camera with “forward motion compensation” is needed for such close-up work. Such cameras move the film during exposure at a speed that compensates for the aircraft speed. Though the image is moving within the camera, it stays at a fixed location on the moving film itself.

The new technology of digital cameras has recently become available. Imagery is recorded electronically instead of on physical film. Data are then already compatible with computer analysis. Imagery can be viewed and downloaded soon after acquisition. Resolution is not as good as film photography, but some cameras (such as about 4000 x 4000 pixels) are reasonable substitutes. Some expensive mapping cameras are becoming available which have a much greater number of pixels across the scene. The time between subsequent exposures is limited by the time to download an image to the storage device; it increases with image size. Various image compression techniques are offered with the better cameras to speed storage times and save storage space. Some digital

cameras are configured for CIR imagery. Numerous aerial imagery vendors are now offering digital imagery.

Videography

For some projects, videography offers an inexpensive RS system. Videotape is much cheaper than photographic film and can be viewed soon after acquisition. Home video cameras used to be of a quality that was inadequate for RS work. That was easily demonstrated by grabbing and viewing a single video frame. Imagery was grainy. A broadcast quality (expensive) camera is needed for most RS work. However, both cameras produce imagery of limited resolution. Though the computer might render an image as 480 x 640 pixels, the vertical part of the image is really made of roughly 350 lines. Furthermore, each frame is captured in a total of 1/30 sec, but in two halves. First, every other line is sampled in 1/60 sec. Then the camera captures the intervening lines in the next 1/60 sec. If there is forward motion of the scene, as from a camera pointing directly downward (at nadir) from a helicopter or aircraft, the movement will create offset duplication of scene features, as in a double exposure. The video capture system then needs to be instructed to capture only the first or second half (field) of the scan and duplicate it as the missing lines of the other 1/60 sec. That reduces the effective resolution even further.

Video systems in use in the USA and some other countries are in the NTSC format. Systems in Europe and many other countries use the PAL format. Though cassette tapes are physically identical, the data are so different that a PAL tape played on an NTSC machine does not produce anything visible on the display. This becomes a problem only if foreign projects are under consideration. Special equipment is required to convert between the video formats.

The half-inch video tapes common for home use are inferior to broadcast (3/4 inch) tapes in terms of image quality. The latter require special players to view. The use of the better tapes reduces the graininess of the video imagery, making it more suitable for remote sensing investigations. Recording media are rapidly improving and storage devices are becoming tiny. The image resolution and quality for the new systems have not yet been evaluated by our office.

A new technology of digital video is becoming available, promising greater quality of imagery and greater resolution, with recording onto much smaller tapes and devices. This may be the preferred system in the future. We are beginning to test the modern digital video cameras.

Scanners

A scanner views the Earth (or other scene) one to several lines at a time at an orientation perpendicular to the flight direction of the aircraft or satellite. One style of operation has

the view of the sensors mechanically moved along the line of examination, recording the variation of radiance reaching the instrument in various spectral bands. Another style is to have a linear array of detectors (“pushbroom”) that views the scene (a slit view) simultaneously. The array of detectors is interrogated sequentially for the radiance values at each location along the viewing line. Either style produces a stream of data, line by line, for recording. The forward movement of the platform provides the displacement for the perpendicular dimension in order to create 2-dimensional imagery. Scanners have been designed with variable numbers of spectral bands, from monochrome to multispectral to hyperspectral.

Satellites

Earth-observing satellites began with weather satellites in the 1960s. The AVHRR instrument on the modern NOAA weather satellites is additionally used for coarse (1 km) vegetation health mappings. The satellites were soon adapted to the Landsat series of polar orbiters in sun-synchronous, low-earth (LEO) orbits, gathering their images at about 10:30 a.m. each day at about 30 m resolution. Imaging technology grew from videography to multispectral scanners (MSS) to thematic mapper (TM, a better scanner), and subsequent enhancements. The French put up a series of SPOT satellites for land cover imagery. India then had a series, IRS, with a wide range of resolutions. Some other systems specialized in oceanic views (Orbview-2). The new trend is towards much finer resolution (4 m 4-band color, 1 m panchromatic or better) from IKONOS, QuickBird, and Orbview-3. The Terra satellite (10:30 a.m.) carries the MODIS (wide angle, coarse resolution, three dozen bands) and ASTER (14 bands, VNIR, SWIR, TIR, comparable to Landsat resolutions) instruments; the Aqua satellite (1:30 p.m.) carries another MODIS instrument.

The navigational satellites, GPS and the Russian and European equivalents, are in a middle altitude above the earth, with orbital periods of about a half day. They are not used for imagery. The geostationary imaging satellites, such as the GOES series are mainly used for weather surveillance, always viewing from the same position over the equator. Most geostationary satellites are used for communications of various types.

An important consideration is repeat coverage. The modern Landsat series images the same location every 16 days. Other satellites can be aimed off-nadir for more frequent views, such as every couple of days. Off-nadir viewing allows the creation of stereo pair imagery from which elevations can be derived. The several decades of Landsat coverage allow for change detection studies. However, that coverage will become reduced because of a component failure in Landsat-7 at the end of May 2003. Landsat-5 (launched March 1985), which still takes images well after its designed lifetime, can substitute for a limited time. There are several satellites using microwave energy. Those like Radarsat (and comparable European and Japanese satellites) and a few Shuttle flights operate(d) radar to measure surface topography and texture. They could view through clouds and operate at night. The latest Shuttle series has acquired topographic data for most of the earth. Radar is good at mapping flooded ground and oil slicks on water. Other satellites

passively measure falling rain or the water content of snow packs, though at coarse resolution.

The Civil Applications Committee is promoting use of Department of Defense satellites for government projects and studies. However, viewing of such products must be done in secure facilities and the analysts must have security clearance. More recent directives have suggested that commercial satellites be used whenever possible.

There are now dozens of past and present satellites with available data in the visible and infrared bands. Fig. 29 shows the spectral ranges and pixel resolutions of most of them. Our satellite remote sensing has traditionally used the Landsat series. The old satellites provided MSS data in 4 bands (green, red, two near-IR) with coarse pixels that were not square. The Thematic Mapper (TM) then provided 6 visible and infrared bands at 30 m resolution and a thermal band at 120 m resolution. Landsat-7 improved the thermal resolution to 60 m and provided a 15 m panchromatic band. However, Landsat

Fig. 29. A graph showing the spectral and pixel resolutions of various satellites.

data are becoming unreliable for future use. Landsat-5 is much older than design specifications. Landsat-7 has lost its scanning correction for getting its scan lines parallel with respect to the earth, creating gaps in coverage away from the orbital path. There is no good replacement when these satellites fail completely.

The EO-1 satellite, in orbit 1 minute behind Landsat-7, carries the ALI (Advanced Land Imager) camera which occupies only a quarter of the Landsat swath. It has more numerous bands in the visible to mid-IR, at much better signal-to-noise ratios than Landsat. However, there is no thermal band. The satellite also carries the Hyperion hyperspectral instrument with about 190 useful spectral channels (visible to short-wave-IR) but only a 7.5 km swath at 30 m pixel resolution.

We have made limited use of the French SPOT satellite system data. The latest SPOT-5 has a variety of resolutions from 1 km to 2.5 m in various wavelengths but no thermal imagery. The Indian IRS-1C and -1D and the new Resourcesat have resolutions near 180 m, 23 m, and 5.6 m, but without thermal imagery. Both satellites do not automatically take pictures but must be tasked for specific views.

The ASTER camera can be a good substitute for Landsat imagery, but it must be tasked for its views; it does not routinely take pictures. The 3 VNIR bands are at 15 m resolution, good for vegetation and cultural mapping. 6 SWIR bands are at 30 m resolution, possibly good for mineral mapping. 5 thermal IR bands can not only give temperature data (useful for evapotranspiration calculations) but can be manipulated to yield basic rock types: carbonate, silicate sands and shale, and igneous/metamorphic.

The MODIS camera on the Terra and Aqua satellites provides only coarse resolution of limited use to Reclamation needs. Some of the bands are designed for water penetration and are saturated over land and clouds. Some of the bands have excessive noise.

Three figures for the different resolutions are provided for viewing. The scene is of the San Francisco area on 27 October 2003, a date with extensive fires farther south. Fig. 30 shows the two bands at 250 m resolution. Fig. 31 shows the five bands at 500 m resolution. Fig. 32 shows the 29 bands at 1 km resolution. Notice the horizontal striping in the images, indicating that the elements in the sensor arrays are not

Fig 30. Two MODIS 250m band views of San Francisco area.

balanced. This striping becomes strong in some of the 1 km bands. Some of the 500 m bands show artifacts of dark ocean signatures below threshold. The top half of Fig. 32 is for reflective bands. Bands 13 and 14 are given in low and high gain versions. Bands 15 and 16 saturate on land. The lower half of Fig. 32 are emissive bands, sensing only the energy emitted by the earth's surfaces. Bands 27 and 28 do not see the ground. Band 36 seems worthless. All of the bands have georeferencing challenges that increase from the nadir (orbital path) sideways to the edge of the view.

Fig. 33 shows the Terra view of the Salton Sea, near the eastern edge of the view. The 250 m pixels are acquired in a swath of 40 pixels. The 500 m pixels are acquired in a swath of 20 pixels. The 1 km pixels are acquired in a swath of 10 pixels. When viewing near the nadir the swaths abut but do not overlap. Near the edge of the view, far from the satellite, the views expand greatly so that the swaths significantly overlap, as shown by the segmented view of the Salton Sea. This suggests that it may be better to get summarized and georeferenced data rather than the basic L1B data. In contrast, Fig. 34 shows the Aqua view of the Salton Sea 3 hours later, which was near-nadir. The Sea is larger in the figure because it is closer to the satellite. Image overlaps are difficult to detect in the Aqua view.

Fig. 31. The five MODIS 500m band views of the San Francisco area.

Fig. 32. The 29 MODIS KM band views of the San Francisco area.

Fig. 33. The edges of the MODIS scans overlap.

Fig 34. Objects are larger in the nadir view, with minimal scanning overlap

Radar

Radar involves illuminating a scene with pulses of radar energy. The timing of the reflection indicates the distance to objects in view. Radar beams are normally transmitted at a slant angle to the ground. Tall objects will appear closer to the radar unit than their

map position indicates. Terrain can block radar beams, causing shadows. The strength of the return signal indicates something of the nature of the surfaces. The orientations of the polarization of transmitted and returned energy give additional information about the surfaces. Mirror-like surfaces, like smooth water, return nothing. Geometric surfaces, like buildings, can act like corner reflectors, sending back a strong return pulse. Therefore there are interpretation challenges for raw radar data.

Radar has long wavelengths, compared to other parts of the electromagnetic spectrum. It therefore requires transmit and receive antennas comparable in size to the wavelengths. Larger antennas give greater focus to the radar beams, but large antennas may be too large to carry on aircraft and spacecraft. The solution is to continuously record radar data as the antenna is moved along to different locations. The technique is called Synthetic Aperture Radar (SAR), simulating a line with lots of antenna segments that, with computer processing, appear to be parts of one giant antenna. Most airborne and satellite radar systems are operated in such a mode. The Shuttle Radar Topographic Mission (SRTM) recorded elevation data for most of the earth. It has been processed to 1 arc-second (about 30 meter) resolution for continental USA and 3 arc-second resolution for the rest of the world except polar and ocean areas. Similarly, SAR data from different aerial flight lines can be used to produce digital elevation modes of the terrain.

For additional refinement, radar data can be analyzed in an interference mode. For example, data from different dates can be compared for minute differences, thereby indicating topographic changes from earthquakes and volcanoes and speeds of glacier flows.

Fig. 35 is from east of Yuma, Arizona, taken by the Radarsat-1 satellite. The brightness indicates the strength of the radar reflection. Hills in the lower right appear to lean eastward towards the satellite, as is typical for radar data. Agricultural patterns are visible near the Gila River.

Fig. 35. A Radarsat view of the hills east of Yuma, AZ degraded to Landsat resolution.

The enlargement of the river area (Fig. 36) shows more detail of roads, a railroad, the river, and fields. The hills are brightest on the east side, being illuminated from the east by the satellite.

Fig. 36. A Radarsat view of the Gila River, full resolution.

The suburban area in Fig. 37 is strongly reflective, with the geometric buildings acting like corner reflectors. A limited access highway interchange is weakly visible in the center of the view. Street patterns contrast strongly with the buildings.

Fig. 37. A Radarsat view of housing east of Yuma.

Satellite radar imagery is valuable for mapping the extents of flooding. The area covered by water gives essentially no radar return, appearing black in intensity. This Fig. 38 scene is from the Red River flood, showing a region near the junction of Minnesota, North Dakota, and Manitoba. The scene is artificially colored with blue indicating the water areas. Using the section patterns of the fields indicates a flood roughly twenty miles across. Trees give a signal along the river corridor. Such evaluation of floods can be done day or night and through any kind of cloud cover. The satellite provides the illumination energy and clouds are transparent to the radar beam.

Fig. 38. A Radarsat view of the Red River floods, colorized blue.

LIDAR

Light Detection and Ranging (LIDAR) is another tool that many larger photogrammetric mapping companies have incorporated into their elevation data collection methods in recent years. LIDAR works in a similar way to radar: ranging based upon the speed of light. The beam can be focused to a more narrow point than radar. Both visible and infrared lasers are possible, but there is much atmospheric scatter for blue light. The sensors can receive back multiple reflections from a single pulse, indicating a succession of surfaces at increasing range or depth.

There are two basic types of LIDAR systems, one is used to collect topographic elevation data and the other is used for bathymetric data collection. There is even a hybrid LIDAR system that is supposed to be able to collect both topographic and bathymetric data simultaneously. Aerial use of LIDAR requires knowing precisely where the aircraft is located in 3-dimensions and its 3-axis orientation. An airborne LIDAR systems primary components are a focused infrared laser that emits laser energy pulses toward the ground by means of a scanning mirror, an interfaced inertial measurement unit (IMU), airborne GPS (global positioning system, likely differential), required hardware/software, and the expertise to make it all work properly. Quite often companies will pair a digital camera with the LIDAR system to capture digital imagery simultaneously.

LIDAR systems can capture tremendous amounts of point (x,y,z) coordinate data in a relatively short time frame. Currently many LIDAR systems can collect data at a 1-5 meter post spacing, with a horizontal point accuracy of 1-meter or less, and an expected vertical point accuracy in the range of 15-25 cm. LIDAR data can be collected in daytime or nighttime, and in overcast conditions (if the clouds are above the LIDAR system platform). However, good LIDAR data cannot be collected during adverse weather conditions such as snowstorms, rain, smoke, mist, and fog.

Laser altimetry operates with similar geometric considerations as across-track scanning. Objects away from nadir are seen increasingly from the side as the off-axis angle increases. Near nadir views can permit sometimes seeing the ground through a vegetative canopy, but that can become rare with off-nadir measurements. Bare-earth elevation data is what most Reclamation projects require. Most LIDAR contractors have developed algorithms to classify and remove vegetation, buildings, and other above ground features from the raw LIDAR data in order to produce the bare-earth elevation data. In some instances, such as vegetation/canopy height or infrastructure mapping the multiple-return LIDAR data is needed. However, keep in mind that LIDAR is not always a “silver bullet” solution to your elevation data needs. Contrary to what some contractors say LIDAR does not always penetrate vegetation cover and put the point on the ground, especially in dense vegetation conditions. In some cases the resulting bare-earth LIDAR data points may not have dense enough point spacing for applications such as hydraulic modeling. Just because you specify the LIDAR data be collected with a 2-meter post spacing, you’ll likely find the bare-earth post spacing in some places will exceed several times 2-meters. You will still end up with more data points being collected, more quickly, than with about any other method. Don’t be surprised if it falls short in some areas. Also remember that LIDAR systems collect “mass points” data, and not necessarily break line data. Your own application may require the collection of aerial photography or digital imagery, so that 3-D stereomodels can be setup on a stereoplotter or a photogrammetric workstation to collect breakline data for your elevation needs. Dense foliage adversely impacts photography and imagery; you can’t map what you can’t see.

Sample LIDAR data: All in feet, United States Plane 1983, Washington South.

Northing	Easting	Elevation(FT)
374333.5	5015936.6	1508.27
374324.3	5015935.8	1508.48
374321.9	5015934.9	1508.53
374383.3	5015860.4	1508.34
374384.0	5015856.7	1508.30
374378.8	5015852.6	1507.99
374372.2	5015855.4	1508.61
374296.8	5015864.0	1508.71
374276.2	5015879.3	1508.72
374295.3	5015862.5	1508.40
374295.3	5015861.6	1506.67
374272.5	5015879.9	1508.82

These successive records are of variable spacing, and a data set is likely to be many hundreds of megabytes in size. They can be imported as a 3-D vector set or as a surface.

The Fig. 39 orthophotograph is at Dry Falls, in central Washington state. LIDAR was used to accurately map the topography downstream for input to a model of water flows in case of dam failure. The LIDAR data in Fig. 40 were contoured at 1 foot intervals and are here overlaid on the orthophoto. Trees and buildings have been edited out of the data set.

Fig. 39. An orthophoto view of the Dam at Dry Falls.

Fig. 40. LIDAR generated elevation contours at 1' resolution.

LIDAR instruments are also available for use on a tripod mounted on the ground. They can generate a fine scale array of 3D data points which can be edited to remove unwanted artifacts such as trees and other non-surface features. They also record the brightness of whatever the laser beam hits so that a B&W image of the scene can be created for reference.

The Bureau of Reclamation has also used bathymetric LIDAR. It was arranged by Robert Hildale who supplied these examples. The instrument was a Shoals 1000T manufactured by Optech. It was flown over the upper Yakima River in Washington State, where the water is very clear. Ground truth was provided by a physical probing of the river by poles, with GPS locations. In Fig. 41 the LIDAR provides many more data points (yellow) than the ground crew (blue points connected by a green line) and much more rapidly.

Fig. 41. The distribution of water depth measurements in Yakima River by wading survey and LIDAR.

A comparison (Fig. 42) of the two methods was made by selecting LIDAR points closest to the survey line and within a set distance. The LIDAR measurements are connected by the magenta line, the ground survey by the black line. Differences exist. An instrumental offset was discovered such that the LIDAR processing software needs some adjustments. Sometimes holes and submerged obstructions were discovered by the LIDAR but not the ground survey. It must also be remembered that the LIDAR works primarily in clear, not muddy water.

Fig. 42. The relation between hand measured water depths and LIDAR values.

Thermal

Thermal imagery is available from some airborne scanners or FLIR (Forward Looking InfraRed), and from satellites. Airborne scanner units may be of the Daedalus brand; the thermal band being just one of several wavelengths observed. FLIR instruments were developed for the military and police surveillance and produce a television format output of the thermal data, sometimes with an additional natural color video image of the same scene. Thermal images are affected by the diurnal curve. Water bodies have relatively slow and minor temperature changes as the day progresses. Soil and rocks have little thermal inertia and heat and cool rapidly. Therefore, water can be warmer than land near sunrise but strongly the reverse in the afternoon.

The Fig. 43 FLIR image from the canyon of the Little Colorado River shows the video (visual) view on the left and the thermal view on the right in the hours after sunrise. The shores of the river are dark in the thermal because the damp soil cools to the "wet bulb" temperature in addition to being cooler from overnight radiation loss. Therefore thermal remote sensing can sometimes give an indication of soil moisture. Dry rocks and soils are not as cool. Rock ledges are often visible because of differing thermal inertia from the surrounding rocks. In addition there is a flow of warmer water entering the river from a warm spring on the side, contrasting with the cool shores.

Fig. 43. An example of a hot spring in the Little Colorado River measured by FLIR in Visible and thermal wavelengths.

When properly calibrated, water temperatures can be measured to about 0.2 C precision. The Fig. 44 image is from the confluence of the Colorado River and the Little Colorado River. It was obtained with a FLIR instrument from a helicopter flight about 2500 feet above the river. The Colorado river (blues) is constantly cold, drawing its water from the bottom of Lake Powell behind the Glen Canyon Dam. The Little Colorado is about ten degrees C warmer (reds). It flows along the north edge of the sandbar, then starts to split its flow and rapidly merges into the turbulent and much colder Colorado River. The thermal pattern reveals the dynamics of the mixing waters.

Fig. 44. FLIR thermal data colorized according to temperature.

A Daedalus scanner recorded 3 visible and 3 infrared (including thermal) bands at the confluence of the Columbia and Yakima Rivers in central Washington state. The visible scene is at the left of Fig. 45 and a colorized thermal scene is at the right. The river temperature patterns are strongly evident. The Columbia River (left) is cool (cyan) and mostly uniform. The Yakima river (bottom) is warm (green to orange), especially as it becomes shallow over mud flats near the large island. Thermal scanners can also determine the radiative temperatures of manmade objects, such as house roofs and power plants to see the thermal losses of energy or unusual emissivities. Many of the roofs in the right side of the view look unusually cool (dark blue) because emissivity.

Fig. 45. The visible and thermal (colorized) views of the confluence.

Image geometry

The scale of a photograph is the ratio of the focal length of the lens to the height above ground. For example, a 6 inch lens flown at 2500 feet above ground gives a scale of 1:5000 on the film.

If the camera axis is not vertical, the center of the photograph will not be at the nadir and there will be distortions in the image, shown in Fig. 46, compared to a map view. If the off-nadir direction is parallel to one of the edges of the image, the camera will view flat terrain in the shape of a trapezoid. Otherwise the view will be a more complicated quadrilateral.

Fig. 46. Image distortions from off-nadir viewing.

Aerial photos are close to agreement with maps only if the subject is flat and the camera is pointed at the nadir. Where there are vertical displacements, the position of an object in the photograph will be displaced radially from its true position. Fig. 47 and the corner enlargements in Fig. 48 are from the Spring Creek development south of Buffalo Creek. Notice that the conifer trees are leaning back radially, with the greatest distortion at the edges. The scene also has vignetting: a darkening with distance from the center that is most severe in the corners.

Fig. 47. Radial leaning of conifer trees.

Fig. 48. Enlargements of the photo corners.

The apparent brightness of the scene varies across the view. The anti-solar point (upper left) is brightest. Some vegetation types reflect light back along the incoming path to a greater extent than in other directions. Furthermore there is a minimum of shadowing there. The maximum shadowing is seen in the opposite side (lower right, Figs. 47 and 48) of the photo; both the dark sides of the trees and their shadows contribute there.

Higher terrain causes the terrain to move radially outward on the aerial image. Lower terrain moves inward. In the Fig. 49 image of an entire section of land the roads do not form the perfect square shown in the topographic map, Fig. 50. The view is off-nadir. Furthermore, the road at the top of the image goes over a hill, making it bow outward in the photo. Outward bowing of straight lines is also a symptom of some lenses, particularly those with relatively short focal lengths which approach wide angle or fish-eye lenses.

Fig. 49. Distortion of photo caused by topography.

Fig. 50. Topographic map of the section.

Scanner geometry is different. As shown in Fig. 51, tall features lean back in a direction perpendicular to the flight path, away from the flight line.

Fig. 51. High features lean away from and perpendicular to the flight track of scanners.

Platform attitude

Aerial images can be distorted by the orientation of the aerial platform. Off-nadir viewing has already been illustrated. Other effects are noticeable with scanner instruments, which put an image together by splicing successive lines of image data. The angular movement of the aerial platform, such as an aircraft, is known as "attitude".

A change in the pitch (angle of attack) of an aircraft results as the nose moves up or down with respect to the center of the aircraft. In Fig. 52, from just northwest of Golden, Colorado, the ER-2 (modified U-2) stratospheric aircraft encountered a wave in the atmosphere as the air bounced as it came over the continental divide and front range. The aircraft's pitch oscillated, causing alternate stretching and compression of the image along the flight direction. Notice that the blurring is parallel to the front range.

Fig. 52. Distortions in caused by pitch.

The roll angle of an aircraft is changed as the aircraft rotates around the flight direction, as in left or right banking. Some aerial instruments can adjust for a limited degree of roll changes by means of gyroscopic control, but the angular changes in Fig. 53 are excessive. This is scanner data. The margins are blackened where the image system could not compensate enough. Elsewhere the distortions can be seen by roads that are not straight.

Fig. 53. Distortions caused by roll.

Fig. 54. Distortions caused by yaw.

Yaw is a twisting movement as the forward orientation of the aircraft moves to the right or left. For scanner data, in Fig. 54, yaw will create compression on one side of the flight track and expansion on the other, with minimal distortion near the flight track. For aerial photography, in Fig. 55, yaw shows up in successive images that are not at the same orientation with respect to the flight track.

Fig. 55. Displacement in aerial photos caused by yaw.

4. Datum and Projections

The Earth is not a perfect sphere nor a perfect ellipsoid. Therefore there are mathematical models that attempt to describe the Earth. A key word is Datum, which is the name of the model being used. North America topographic maps have traditionally used the North American Datum - 1927 (NAD27) that uses the Clark Ellipsoid of 1866. An update is a 1983 version, NAD83, that uses the GRS 1980 ellipsoid. This is similar to the World Geodetic System 1984, WGS 1984, for acronym and ellipsoid, that is the default system for GPS use worldwide. There are hundreds of local and regional datums in existence. Differences between them can be significant, especially when using location measurements at centimeter scales.

The Earth has a generally curved ellipsoidal surface. Maps are usually flat planar surfaces. Therefore projections are used to convert Earth positions onto planar maps. The USGS offers a paper poster about map projections. Numerous projections are described and illustrated. The latitude/longitude coordinate system is not a projection. Those coordinates can be converted into a true projection by appropriate mathematical formulas. One of the projections typically used for Reclamation work is Universal Transverse Mercator (UTM), which divides the earth into 60 narrow zones that are 6 degrees of longitude wide; knowing the appropriate zone is important. The Space Oblique Mercator can be used for Landsat satellite images. Conic projections are common, such as the Lambert Conformal Conic and the Albers Equal Area Conic. The State Plane, which can divide a state into 1 to 6 (10 for Alaska) zones, is a variation of the Lambert Conformal Conic. Map products should always indicate the projection being used, especially if the area extent is large enough that Earth curvature is significant.

For a random example of the importance of Datum and Projections, consider a GPS measurement (WGS 1984) location at N 40°, W 105°, elevation 5000 feet (1524 meters), which is northwest of Denver, Colorado, but not necessarily at the ground surface. Using the NAD83 Datum gives the same values. Converting to the NAD27 Datum gives the same elevation, but a position of N 40° 00' 00.055", W 104° 59' 58.073". The UTM position needs Zone 13; using WGS 1984 gives coordinates of northing 4,427,757.219 meters, easting 500,000.000 meters and the same elevation. Switching to NAD27 gives coordinates of northing 4,427,548.876 meters, easting 500,045.692 meters and the same elevation. The northing difference is 208.343 meters and the easting difference is 45.692 meters, for a total (diagonal) difference of 213.295 meters. That is a large difference compared to typical GPS precision. State Plane for Colorado North (NAD83) has coordinates of northing 378,940.842 meters, easting 957,097.095 meters and the same elevation. Switching to Colorado Central (NAD83) results in northing 545,448.335 meters, easting 957,101.063 meters. There are some Datum changes (I was comparing values in Ecuador) which change the elevation values because of ellipsoid differences.

5. Global Positioning Systems

The Defense Department operates a constellation of at least 24 satellites as part of a Global Positioning System (GPS). The satellites have orbital periods of about 12 hours and are distributed in 6 orbital planes so that at least 4 satellites are usually visible in the sky at any given point on the Earth. Receiver stations (many brands - such as Garmin and Magellan - and various qualities, mostly portable) measure the distances to the satellites and triangulate the geographic position of the receiver antenna. Vertical accuracy is less than horizontal accuracy.

In addition, the Russians operate their own network of satellites (GLONASS) and the Europeans are planning a system (Galileo). The systems have two or three levels of accuracy. As originally configured, the American system had a condition known as selective availability. The GPS signals were intentionally degraded to about 100 m accuracy. That option is not presently activated, giving typical hand-held GPS receivers about 5 m accuracy. Military grade receivers, known as PLGR, are available on a restricted basis. They are not subject to the selective availability, even if that degradation option is being applied.

A more accurate mode of operation is known as Differential GPS (DGPS). It depends on a GPS receiver at a fixed location (base station) that determines the error in the signal. That error can be applied to GPS data recorded by a roving receiver within about 300 km of the base station and sub-meter accuracy can be achieved. The corrections can be made in post-processing mode with the recorded data. Some base stations broadcast the error correction in real time. Suitably equipped receivers can use the WAAS correction signal to achieve the greater accuracy.

A survey grade GPS uses a different signal type to achieve centimeter accuracy, but such units cost tens of thousands of dollars and need to be at a fixed location for hours of integration.

The GPS signal is not receivable within most buildings. Tree canopies and cliffs can block the signal, limiting the number of satellites in view. Tall buildings can deflect the signal, causing inaccuracies. It is best to operate with an open sky. That may mean placing a receiving antenna on the roof of a vehicle to get an unobstructed view of the GPS satellites while traveling. GPS receivers can be carried by hand around places of interest, erected on fixed tripods, and attached to vehicles roving an area. They can be attached to aircraft to record the positions at which imagery was gathered. Fig. 56 illustrates a GPS track (red) from a PLGR with roof antenna while traveling on roads shown in an IKONOS image near the intersection of Dodson Road and Frenchman's Creek Road, southwest of Moses Lake, Washington. Only slight deviations from the road are present because of the clear view of the GPS satellites.

Fig. 56. GPS Track in central Washington state.

In contrast is the track shown in Fig. 57 of a Garmin GPS-12 unit carried in a side pack through the Forbidden City of Beijing, China, shown on a QuickBird satellite image (0.6 m resolution). The image has been split so that the upper left matches the lower right. North is at the right. The red line is the GPS track and the cyan line closely approximates the actual route walked. There was loss of signal when passing through buildings. There may have been distortion of signal from reflections from buildings and absorptions by the human body beside the GPS unit. Significant positional errors were therefore caused by having blockages of at least parts of the sky and by reflections of signal. Similar effects should happen with a GPS unit used within a canyon with steep walls.

Fig. 57. Distortions and dropouts in GPS track caused by buildings.

6. Image Processing

Adjusting Contrast

Imagery on the computer display (or sent to a printer) can be adjusted for better visibility or for special effects. For illustration the sample scene will be a close-up image of embryo ice crystals formed in a super cooled cloud by a cloud seeding technique of chilling some air colder than -40° . The event took place in a chest freezer in the late 1940s with a black velvet background. Some contrast adjustments may have already taken place as a B&W photo was scanned to form this image. A variety of adjustments will be shown, using graphics captured from TNTmips software displays.

The figures are in pairs, with graphics first and then the resulting output image. The graphics has three parts. The large square in the center to lower right is a graph showing the relation between input pixel numerical values (vertical axis) and output pixel numerical values (horizontal axis). To the left is a histogram, showing the distribution (horizontal axis) of input numerical values (vertical axis). At the top is a similar histogram, showing the distribution (vertical axis) of output numerical values (horizontal axis).

First will be a version “as is” as it comes from the 8-bit grayscale file image using a linear contrast scale from 0 to 255. The left side of Fig. 58 (and similar graphical figures) shows the histogram of the digital numbers in the image. Most pixels have small values, as shown by the bimodal distribution at the left, but there are a few pixels that are bright, as shown by the trailing tail at the upper part of the distribution. Scanned photography will often have such a distribution. The output histogram, displayed across the top of the graphics, has the same shape as the input histogram. The relationship between the input and output images is shown by the diagonal line across the large square. The type of contrast relationship (Linear) is displayed near the bottom, as are the ranges for the input and output numbers. Fig. 59 shows the scene with this linear contrast.

Fig. 58. Graphical representation of full linear contrast.

Fig. 59. Snow crystal embryos with full linear contrast.

This software lets the input range be adjusted by sliding the dashed lines in Fig. 60 to different positions. I have selected a lower limit of 17 and an upper limit of 90 in order to isolate the black velvet background and the cloudy air, ignoring the brighter snow particles. Alternatively, I could have simply typed those values in the Input Range boxes. The resulting display in Fig. 61 shows saturated snow but the cloud is more visible. The graph in the large square shows a diagonal line stretching between the limits indicated in the range boxes at the bottom. When adjusting for atmospheric haze, it is useful to place the lower limit at the darkest feature in the scene, such as a lake.

Fig. 60. Graphical representation of partial linear contrast.

Fig. 61. Snow crystal embryos with partial linear contrast.

Then displaying an image with an initially unknown histogram, the “Normalize” contrast method . The histogram of the input image is resampled, so that its output distribution somewhat resembles a normal curve (as defined in probability and statistics). In this case the bimodal distribution prevents a near-perfect fit to the normal curve (Fig. 62), but the result (Fig. 63) is a pleasing rendition that shows all image features: black velvet, cloud, and ice crystals. The normalize process also found that the darkest pixel had a value of 17 and therefore started its distribution at that number. Notice the wavy line in the large square box. The logarithmic contrast method will greatly brighten the dark values while keeping the bright pixels from saturating. The curve in the large square box of Fig. 64 has a shallow slope initially but then a smooth transition to a steep slope. The image in Fig. 65 has a gray background as a result.

Fig. 62. Normalized contrast

Fig. 63. Snow crystal embryos with normalized contrast.

Fig. 64. Logarithmic contrast.

Fig. 65. Snow crystal embryos with logarithmic contrast.

The exponential contrast method gives the analyst much control over the appearance of the output. An exponent of 1.00 (default) is the same as a linear contrast method. An exponent of 0.50, shown in Fig. 66, lies between a linear and a logarithmic relationship. The exponent number may be typed into the box at the bottom or the cursor can drag the curve to its new position (in this software, if not in the others), yielding exponents ranging in hundredths from 0.01 to 100.00. The result in Fig. 67 is a generally pleasing view without saturations.

Fig. 66. Exponential contrast with power 0.5.

Fig. 67. Snow crystal embryos with exponential contrast with power 0.5.

If the exponent is greater than 1.00, the bright values are enhanced and the darks are made darker. In Figs. 68 and 69 a value of 2.00 effectively eliminates the black velvet and the cloud, leaving only the higher concentrations of ice crystals.

Fig. 68. Exponential contrast with power 2.0.

Fig. 69. Snow crystal embryos with exponential contrast with power 2.0.

Sometimes the input image may be a negative and the contrast needs to be inverted, as shown in Fig. 70. This produces in Fig. 71 black ice crystals on a bright background, much like astronomers often display pictures of stars.

Fig. 70. Inverse linear contrast.

Fig. 71. Snow crystal embryos with inverse linear contrast.

These illustrations have been with single band monochrome images. When a color image is displayed as Red-Green-Blue, each band may be individually enhanced with possibly a

different contrast method. However, it is usually good to keep the contrast method the same but possibly vary the Range limits. Similarly to the last illustration, color negatives can be inverted to get positive images.

Gray scale imagery that is 8-bit can be artificially colorized. In the color look-up table of Fig. 72 the values of 96 to 254 have been given a spread from Blue through Red to purple, enhancing the ice crystals. The values saturated at 255 have been left as white and all dark values remain the same. Random colors could also be assigned. The colors highlight regions of the scene in Fig. 73.

Fig. 72. Color table used to colorize snow crystal embryos.

Fig. 73. Colorized snow crystal embryos.

Displaying Color

In Fig. 74 I have selected a portion (300x300 pixels at 15 meter resolution) of a scene from the North Rim of the Grand Canyon, as seen by the ASTER camera on the Terra satellite. The actual color bands are green, red, and NIR, which display to the standard false-color infrared rendition (healthy vegetation is red). At the bottom of the view are the headwaters of Bright Angel Creek. The image was converted from R,G,B separate bands to 24-bit, 16-bit, and 8-bit composite color images. Within the scene, slightly lower than center, a region of individual pixels was selected about the pixel at line 215 and column (row) 169, as shown in the image extract with the cross-hair symbol in Fig. 75.

Fig. 74. ASTER view of part of the Grand Canyon

Fig. 75. Subset of the ASTER view, marking a particular pixel.

The pixels in a 24-bit composite image are made of 24-bit integers (3 bytes). Each of the 3 bytes represents an 8-bit Intensity, ranging from 0 to 255. The byte order may be RGB or BGR. The TNTmips software allows the examination (and direct modification) of nominated pixel values. The first illustration, Fig. 76, of the table of pixel values has a box around the pixel at (215,169). Within the brackets are the numbers 109, 84, and 153. Therefore Red has a value of 109 out of 255, Green a value of 84, and Blue a value of 153. To the right is a pixel with values [0 0 0], indicating pure black. To the lower left are many pixels with greater amounts of red. Two and three pixels above the target pixel are values of 255 for both blue and green. This software allows direct editing of individual pixels; any other numbers can be typed into the “Raster Value” boxes to permanently change them in the image.

The 16-bit images have 5 bits per color. Notice in the Fig. 77 table that the color values range from 0 to 31.

Fig. 76. Pixel values for a 24-bit color composite image.

Fig. 77. Pixel values for a 16-bit color composite image.

The 8-bit images have a very different structure. The numbers 0 to 255 are assigned randomly to a look-up table of the various colors in the image. (In conversion from 24 or 16-bit color to 8-bit color, the closest of the 255 possible colors is used.) In this software, the most frequent colors are assigned to the smallest integer values and the rare colors to the largest values. Notice in the illustrated Fig. 78 table for the 8-bit image that the numbers seem quite random, unrelated to the scene. The color look-up table is displayed in Fig. 79 for reference.

Fig. 78. Pixel values for an 8-bit color composite image.

Fig. 79. The 8-bit map for the ASTER image.

Resampling Styles

Resampling of images to change sizes, orientation, or projection gives the analyst three choices: (1) nearest neighbor (NN), (2) bilinear interpolation (BL), and (3) cubic convolution (CC). NN selects the pixel of the former image that is closest to the target position in the newer image, simply copying its value or color assignment. BL takes the four former-image pixels surrounding the target position and combines the linear interpolation between the opposite pairs of pixels. The resulting value will be somewhere within the range of the values of the 4 pixels. CC uses 16 former-image pixels about the target location for a more precise selection of a new pixel value. Where a linear feature is in the image that is not parallel to the lines or columns of the image, the NN process will usually cause a slight offset in the line in various places. The BL and CC processes will have smoother transitions.

It is very important to understand the color style when selecting a resampling style. There is a trap! If a 24-bit or 16-bit color image is resampled, there will not be a problem. For example, the ASTER image of the Grand Canyon was edited to make a vertical black line 2 pixels wide. The image was then rotated 5 degrees clockwise using the 3 resampling styles. A 100x100 subset of the result was extracted for each style and shown in Fig. 80. The edited 24-bit image was also converted to an 8-bit image and the 8-bit image was rotated 5 degrees using the 3 resampling styles. The same subset was extracted from the 8-bit rotations and shown in Fig. 81.

24-bit: NN BL CC

Fig. 80. A 24-bit sample ASTER image

8-bit: NN BL CC

Fig. 81. An 8-bit sample ASTER image

The 24-bit NN style shows a segmented black line. The BL and CC styles have a smoother line, with the CC having a slightly better image. The 8-bit NN style looks like the 24-bit NN rotation. However the BL and CC images do not resemble the scene! That is because the resampling by the BL and CC methods interpolate the digital numbers and assign a new one to the result. But the color table remains the same and the pixel gets a random color assignment. For this reason, 8-bit color images must use the NN resampling method. If the 8-bit image is only a monochrome, gray-scale image, then the other methods may be used. Similarly, when resampling an image in which the numbers represent classifications, NN must be used to avoid having pixels reclassified to something else.

Filters

Imagery can be cleaned up of artifacts and filtered. Many filter types are available and the choice depends upon the particular need. The first example is an image with much dust on it. A 35 mm slide view of the north end of the Dead Sea was copied commercially to a duplicate slide, but unfortunately the original had dust on it that was not removed. The duplicate slide was scanned to produce the initial image (Fig. 82). (The dust may not show at this enlargement scale.)

Fig. 82. The Dead Sea with dust on original slide photo.

An efficient way to clean up the image is to convert to HIS and then work with the Intensity image. A subset of the initial dusty image is shown at the left of the triple series in Fig. 83; all three are shown with Normalized contrast to make the dust more visible. A simple 3x3 Low Pass Filter was applied for the middle view. Unfortunately, it is just a simple average of the nine pixels centered on the output pixel; extreme values affect such an average. The dust is blurred but is still visible. For the right view the initial Intensity image was hand edited at the large dust spots, manually typing in replacement numbers that were similar to the pixels adjacent to the dust; perfection was not attempted. Next a 3x3 Median Filter was applied. It takes the median value of the nine pixels around the output pixel and assigns that median to the output. Extreme values are thereby ignored. The dust and other noise in the image was removed. An exponential

contrast, with power 0.50, was applied to the result to make the dark foreground more visible.

Fig. 83. The raw and filtered intensity portion of the dirty image.

The former Hue and Saturation (which still contained some residual dust signatures) were combined with the median-filtered Intensity to produce a revised color image, which is shown as Fig. 84. However, what if the dusty and other features need to be made more visible? There are other filters available. Three are shown as examples in Fig. 85. The general advice is simply “try it and see.”

Fig. 84. The cleaned and brightened version, Dead Sea.

Fig. 85. Three enhancement filtered images.

Fast Fourier Transform Filters

Sometimes instrumental noise creates banded or repetitive patterns in an image. That could be from a 60 Hz hum or other special frequencies. An example here is an image from a FLIR (Forward Looking InfraRed) instrument taken in the early 1990s. The image was written to NTSC television format, scanned in pairs of lines. There are two sensors that may differ in calibration, as is the case here. Their line order alternates: 1,2,2,1,1,2,2,1,... Therefore it is similar to a scanning sensor with 4 detectors per sweep. A full scene (omitting the numerical data below the image) is shown as the example in Fig. 86, with a portion from the middle right enlarged by a factor of 4 in Fig. 87.

Fig. 86. A raw FLIR image of the Colorado River.

Fig. 87. An Enlargement of the FLIR.

The original image is then transformed by a Forward Fast Fourier Transform (FFT) to a complex raster image, Fig. 88, with magnitude and phase information. It looks like a scatter diagram with some prominent clustering of points along particular lines. This figure pictures the series of sinusoidal waves that can express the data in the original image. It seems to have no relationship to the scene in the original picture. (It is like a hologram which seems to contain meaningless patterns but through which a 3D image can be viewed.)

Fig. 88. Fourier transform of the FLIR image.

A special editor is then used to cut out portions of the FFT image, particularly pieces of the preferred lines. In this case, the upper and lower crossbars were removed and the upper and lower 3/4 of the vertical axis. (Trial and error may be the best method for discovering what works best.) The software then used the remainder of the FFT image to do the Reverse FFT process and recreate in Fig. 89 the original image, minus the banding. The same subset of the right side of the image is again enlarged by a factor of 4 in Fig. 90.

Fig. 89. The FLIR image cleaned by the FFT process.

Fig. 90. Enlargement of the FLIR image.

During the original analysis of these FLIR images the banding was removed by using a low pass spatial filter of size 4 lines by 1 column. That preserved horizontal resolution and blurred the vertical resolution, but the result got rid of the banding problem. A temperature analysis was then performed on the Colorado River portion of this image from the Grand Canyon.

Band Combinations

Spectral bands can be assigned in any order to the RGB components of a display, often producing a false color combination. For example, the ASTER thermal IR view of the Grand Canyon was chosen. There are 5 narrow thermal bands named 10, 11, 12, 13, 14, all at 90 meter resolution as 16-bit integer data. Fig. 91 shows a 13, 12, 10 assignment as RGB with linear contrast. The South Rim is at the bottom of the view and the North Rim at the top. The Bright Angel Fault follows the diagonal valley. The Colorado River is the dark curved line. The sun angle from the lower right creates shadows in this topography. There are subtle color changes with rock types. Band ratios are typically used to reduce shadowing effects. (A special ratio, called the normalized difference, will be presented later.) In this thermal data set, band 14 was brightest. The other bands were divided by band 14 and the result was multiplied by 255. The ratioed bands 13, 12, and 10 were combined with normalized contrast to form Fig. 92. Instrumental noise, shown by the dotted lines running diagonally through the image, become more visible. Notice that the shadowing is indeed reduced. Furthermore, there is a greater contrast among the colors. The light and medium greens are the limestone layers. The reds are shale and sandstones. The inner gorge by the river, predominately of igneous and metamorphic rocks of granite and schist, is bluish.

Fig. 91. Linear contrast for ASTER thermal bands viewing the Grand Canyon.

Fig. 92. Band ratios with normalized contrast for ASTER thermal bands, Grand Canyon

Fig. 93. Five principal components for ASTER thermal scene, Grand Canyon.

All five thermal IR bands (any number of bands can be used) were converted to principal components (PC), whereby an artificial set of bands is produced that are mathematically orthogonal. That shows the maximum variability in the data but may leave the analyst wondering what the differences really mean. The results are shown in Fig. 93. PC-1 always shows the dominant brightness patterns in the data, in this case the basic brightness from albedo, topographic and shading effects. PC-2 gives rock type information for this data

set. The remaining PC's show decreasing signal and increasing noise, including the instrumental noise.

Similarly, a decorrelation stretch version can be produced from any number of bands. It

Fig. 94. Decorrelation stretch of the ASTER thermal scene, Grand Canyon.

uses a principal components routine to remove the correlation between spectral bands and show only the significant differences within the original spectral bands. The decorrelation stretch bands 13, 12, and 10 are shown in RGB order in Fig. 94. The process maximizes the differences between the bands, producing much bolder color patterns. The color interpretation for basic rock types is the same as for the band ratio image.

Image bands can also be combined by means of arithmetic functions (add, subtract, multiply, divide, ratio, rescale). They can be thresholded, to convert bands to a simple

Fig. 95. Decorrelation stretch inset of visible Landsat bands; Lander, Wyoming.

binary relationship indicating imagery parts greater than or less than the threshold value. Artificially colorizing a narrow range of digital numbers in a single band can help isolate an appropriate threshold value. As a further illustration of the power of principal components and decorrelation stretch, a Landsat scene of a region near Lander, Wyoming, has been chosen. Fig. 95 shows the Landsat scene in approximate natural color. There are agricultural regions to the upper right and forested regions to the lower left. In the lower left corner snow still covers the tops of the Wind River Mountain Range in this scene from early July. The geology is that of multiple strata dipping towards the northeast. They are eroded to sawtooth forms by the streams draining the highlands. The inset is the decorrelation stretch (a subset from the entire scene) of the same bands, showing stronger colors, particularly of the Triassic Red Beds. Other shales became bluish.

Fig. 96. Principal component inset for Landsat bands; Lander, Wyoming.

Fig. 96 of the same area has the inset from a principal components analysis. Components 2, 3, and 4 are shown as R,G,B. The area of analysis was restricted to only the area of the inset, avoiding lakes, snow, and the agricultural areas. (Including the entire scene decreased the color contrast.) The Red Beds are now purple. Other strata become more distinct, showing three types to the left and at least two to the right of the purple band. Using components 3, 4, and 5 also separate these strata well. However, they were not as separable when the entire

scene was included in the analysis because more of the computational power was devoted to the snow, lakes, and agricultural areas.

A pair of rasters can be used to create a 2-dimensional histogram (scatter diagram) in which the brightness or color at each pixel (picture element) represents the number of

Fig. 97. 2-D histogram for the red (X-axis) and NIR (Y-axis) for ASTER view, Grand Canyon

pixels in the original two bands that have the same particular numerical values. The ASTER scene of the North Rim of the Grand Canyon, shown in the Displaying Color section, was chosen as an example. The X-axis in Fig. 97 shows the distribution (histogram) for band 2 (actual red) and the Y-axis shows that for the band 3N (actual near-infrared). The red area of the scatter diagram shows the brightness combinations with the maximum frequency in the scene. In presenting such a 2-D diagram, some software types also put in a scatter of white points (called “dancing pixels” in the ENVI software) that give the pixel values near the cursor when it is placed over the original image. That helps the analyst know what parts of the diagram apply to particular land cover types.

The data represented by such diagrams can be partitioned to provide a basis for a classification (such as water, bare land, growing vegetation, fallow land, clouds, etc.). For this band combination, pixels representing water and black parts of the scene are plotted in the lower left. Pixels with healthy vegetation (dark in red, bright in NIR) are plotted in the upper left. Barren soil and rock typically plot along the main diagonal. Sometimes the scatter diagram for this band combination is called the “tasseled cap”.

That classification can be applied to the original imagery to describe a landscape. There are many supervised and unsupervised classification systems that can take data from any number of spectral bands. Classified imagery can be summarized by pixel counts converted to area units, or by converting the data to vector polygons for GIS analysis.

Fig 98. Normalized difference vegetative index version of Bright Angel ASTER scene.

A particularly useful 2-band combination is called the normalized difference (ND). For bands A and B, $ND = (B - A) / (B + A)$. This is like a band ratio, but it gives a stronger signal. Fig. 98 sets A = band 2 and B = band 3 for the ASTER scene of the North Rim of the Grand Canyon. This makes the ND a vegetative index, with the normal acronym NDVI. Notice that the healthy vegetation is bright white. The dark area in the upper left should have been bright, but is part of a fire swath, hence dead vegetation. Barren soil and rock, as well as water, are also dark. NDVI is typically used for the red and NIR

bands of several satellites (like AVHRR, MODIS, SPOT, IRS) to measure the health of vegetation globally on a weekly basis. There is also a “greenness” and a “wetness” index.

Any number of spectral bands can be combined in a linear regression analysis, showing the correlation between the bands. Pieces of different habitats in the western U.S.A., as seen by the Landsat satellites, were mosaicked together for a linear regression analysis. The resulting table of numbers showed that band 1 (B) was related to bands 2 (G), 3(R), and 4 (NIR) by a particular formula:

$$B = 14.9358 + 1.0784 * G - 0.1443 * R - 0.1143 * NIR.$$

Though the constants may vary with a different selection of scenes, this equation can be useful for predicting a blue image for satellites that do not record it (SPOT, ASTER) or when the blue image is contaminated with too much haze. A blue band was thereby predicted for the North Rim scene. It was combined with ASTER bands 1 (G) and 2 (R) to give a natural color version of the scene in Fig. 99. Unburned trees are green, burned areas are gray, and there are pink rocks where expected.

Fig. 99. Simulated natural color version of the Bright Angel ASTER scene.

Automatic classifications

Caution needs to be used when working with automatic classifications of scenes. For an example I have chosen an IKONOS satellite view of the intersection of the Winchester Wasteway in Washington and Interstate-90, taken 18 August 2000. The 4-band multispectral imagery was at 4 meter resolution, but was reduced to 8 meters for these examples. Fig. 100 shows the natural color view and Fig. 101 shows the color-infrared (CIR) view, both with normalized contrast stretching. Fig. 102 shows a manual classification done with the original 4 meter imagery. It started with threshold partitioning for water (NIR <171), highways (170 < NIR < 360 and 214 < red < 341), and roofs (and some hay stacks and a dried pond) (204 < red). Thereafter hand analysis drew boundaries around fields showing a healthy crop, medium crop, freshly sprouting crop, and plowed fields; wetlands; sand dunes; and other; giving 10 classes.

Fig. 100. IKONOS natural color.

Fig. 101. IKONOS CIR.

Fig. 102. Hand classified.

Automatic classification was done using the indicated routines, all 4 spectral bands, partitioning into 10 classes and using the same default values for any other parameters. Fig. 103 for Simple One-Pass Clustering. Fig. 104 is for K-Means. Fig. 105 is for Fuzzy

Fig. 103. One-Pass Clustering.

Fig. 104. K-Means.

Fig. 105. Fuzzy C Means.

C Means. Fig. 106 is for Minimum Distribution Angle. Fig. 107 is for ISODATA Classification. Fig. 108 is for Self Organization. The processes produce a “distance” raster, whereby small values (black) indicate a close match to the spectral center of a class and large values (white) indicate a more doubtful match. Fig. 110 shows the distance raster for the Fuzzy C Means, using normalized contrast spreading. The same colors are used for the automatic classifications, though they are seemingly randomly assigned to the various classes.

Fig. 106. Minimum distribution angle.

Fig. 108. Self organization.

Fig. 109. Adaptive resonance.

Fig. 110. Distance raster for fuzzy C means.

The Simple One-Pass Clustering seems to use up most of its classes doing fine detail in the field of the upper left corner, making the rest of the scene crudely classified. Four of the seven techniques do not discriminate between water and road. Some of the techniques highlight irrigation within a field. Some of the techniques could be useful for precision farming analyses that seek to understand variations in plant health within a field. In general, the automatic classifications may not match a more laborious hand classification that stresses logical and useful classes for specific purposes.

Fig. 111. The NIR-Green histogram of IKONOS scene.

Other classification strategies are possible. A 2D histogram can be created from two of the color bands. For this scene the Near-IR and green bands provide the greatest separation of features, shown in Fig. 111. This was specially prepared using axes of 1350 for the digital range of pixel values rather than a default rescaling to a 0 to 255 range. The colors in the figure indicate frequency of pixels having particular pairs of values.

The lower left cluster is water. The diagonal band on the left is the highway. The main central patch of red and green represents the barren fields and sparse vegetation areas. The upper central green patch is for the very light green fields.

The weak patch in the bottom center is for the wetlands. The various patches on the lower right represent the numerous agricultural fields with some form of crop present. It is possible to partition this diagram into rectangular or triangular areas and express various thresholds for the possible classifications. A patch might be represented by a combination of rectangles in a process named parallelepiped classification.

It is also possible to use such a histogram as a guide to make a lookup table made with polygons partitioning the histogram. Fig. 112 shows a possible partition that carefully separates 27 peaks in the distribution. Fig. 113 combines those into ten classes resembling the hand analysis of Fig. 102. Using the 10 partitions the region was classified according to the pattern shown in Fig. 114. It shows more detail than the hand classification, including the location of the central pivot irrigation line in the upper left field. The sand dune areas (tan around wetlands) received the same class as the light green and white fields. The fields with a thick crop have different separations from the hand analysis. Fig. 115 shows the results of using all 27 classes of Fig. 112. Details of the fields and water bodies are evident.

Water Studies

The Landsat series can and has been used for studies of some of the properties of water bodies. For illustration purposes, portions of a scene from 2 July 1989, near the Wind River Range in Wyoming, is shown. The bands are not surface calibrated but serve as proxies for the properties. There are several lakes on the southwestern side of the range that receive meltwater from the snow-capped mountains. TM band 6 gives the surface temperature of the scene; dark is cold and bright is warm. Fig. 116 has been colorized over the narrow temperature range of the lakes such that each digital number has a different color, with blue being coldest, red being warmer and magenta and then purple

Fig. 116. Colorized according to surface temperature.

being warmest. The land areas are warmer than the water. The snow pack is in the upper right and is much darker but with colored edges, indicating that the colored temperatures are close to the melting value. Each lake has a different pattern. The two at higher elevations are cold (light blue). Two have significant temperature patterns within the lake. Notice also that the irrigated agricultural fields in the lower left are cooler (darker) than the barren land.

Another area, to the northeast of the Wind River Range was selected. The main feature is Ocean Lake, surrounded by an agricultural area with water distribution canals. The scene is northwest of Riverton, WY. The natural color version of Fig. 117 shows a lightly blue colored lake, suggesting fine sediments from a glacial source in the mountains. This scene is used as a base map for the next views, in which water bodies are colorized to show other water properties.

Fig. 117. A natural color version of the Ocean Lake, WY region.

The uncalibrated temperature patterns (TM band 6) show little variation across the lakes in Fig. 118. The western lake is the coldest. The two largest lakes show warmer (greenish) shorelines, probably because the shallow water lets the satellite see to the bottom sediments which are easily warmed by the sun. Along the upper left is a canal with very warm (red) water. The river in the lower left is cooler (green).

Fig. 118. The Ocean Lake scene with water colorized by temperature.

Band 1 (blue) was chosen as a proxy for turbidity. The large Ocean Lake shows strong patterns in Fig. 119 with red indicating the greatest mud content. There is a small pond at the left that has the cleanest (blue) water. The upper left canal is muddy (reds and oranges) and the lower left river is intermediate (greens). A proper calibration would require field observations of secchi depths - the depth to which a white disc can be seen in the water.

Fig. 119. The Ocean Lake scene with water colorized by turbidity.

Bands 4 (near-IR) and 3 (red) were combined as a normalized difference vegetative index. This index is greatest for growing vegetation. Though darkened by the water, it serves in Fig. 120 as a proxy for chlorophyll content. Reds (small western pond, lower

left river) indicate the greater amounts of growth while greens indicate lesser amounts. A proper calibration for chlorophyll makes a regression analysis among the TM bands.

Fig. 120. The Ocean Lake scene with water colored by chlorophyll content.

All six reflective TM bands (not band 6) can be combined in a “tasseled cap” analysis to create three mathematically orthogonal bands labeled Brightness, Greenness, and Wetness. For this Ocean Lake scene in Fig. 121 these products are displayed as R, G, and B, respectively. Only a few fields showed a wetness signal. Growing vegetation had variable greenness. Barren areas had the strongest brightness.

Fig. 121. The Ocean Lake scene with false color rendition of brightness, greenness, and wetness.

Pan-sharpening

Panchromatic systems, rendering a scene as a single band (B&W), can achieve a finer resolution because there are more photons available to the instrument in the broad panchromatic band than in the individual color bands. Satellites like SPOT and Landsat-7 have panchromatic bands with resolution at half the size of the multispectral bands. The IKONOS, QuickBird, and Orbview-3 satellites have panchromatic resolution of 1/4 that of the multispectral bands. For illustration, an IKONOS scene was selected, showing the intersection of Dodson Road and Frenchmans Creek Road, south of the Winchester Wasteway and southwest of Moses Lake, Washington. The individual bands (Fig. 122), natural color (Fig. 123) and CIR (Fig. 124) versions are shown at 4 m resolution, as is the 1 m panchromatic version which has more detail than shown in Fig. 125.

Fig. 122. The 4 IKONOS multispectral bands of the road intersection.

Fig. 123. Natural color.

Fig. 124. CIR version.

Fig. 125. Panchromatic version.

Pan-sharpening (pan-fusion) first involves subsampling the multispectral images to the fine resolution of the panchromatic images. One technique then transforms 3 multispectral bands as RGB into HIS, substituting the panchromatic image for the Intensity image, and transforming back into 3 bands to be displayed as RGB. The other technique transforms any number of bands into principal components, substitutes the panchromatic image for the first principal component, and then reversing the transformation back into the original bands. However, there is a problem of spectral matching that can severely affect the result. The SPOT panchromatic band spectral range overlaps that of the G-R-NIR multispectral bands, avoiding this problem. However, other satellites have the panchromatic spectral range overlapping four multispectral bands (B-G-R-NIR). If one wants a natural color version of pan-sharpening, the NIR

Fig. 126. Pan sharpened version, using a simple HIS substitution routine.

Fig. 127. Visible band panchromatic image from the 4-meter bands

component will greatly brighten the panchromatic image where there is growing vegetation, resulting in abnormally bright vegetation in the resulting pan-sharpened image or distorted colors as shown by the orange tones in Fig. 126.

One way of working around this problem is to create an apparent visible band panchromatic image (Fig. 127) by averaging the subsampled B,G,R components. A regression equation is then created relating the visible band panchromatic to the subsampled NIR and original panchromatic image. That relationship is then used with the subsampled NIR and original panchromatic image to calculate a better (finer resolution) visible band panchromatic image (Fig. 128). It is that calculated image that is used to substitute for the Intensity image in the HIS transformation or the first principal component before reversing the transformation. The resulting pan-sharpened image in Fig. 129 is much closer to natural color and has superb resolution. Texture is now visible in the crop in the lower right, showing the rows more prominently. There are details within the ponds in the upper left that are missed in the 4-meter multispectral bands. Shadowing is now visible beside the trees in the lower right and elsewhere, allowing an interpretation that considers plant height.

Fig. 128. Simulated visible band panchromatic.

Fig. 129. Pan-sharpened version.

Georegistration

In order to be useful in a Geographic Information System, each raster (image) needs to be georegistered. It is best to assume that all physical materials used to generate raster and vector data are not perfectly scaled. Paper (and similar media) products can contain wrinkles and tears. They may change size with temperature and humidity. Scanned products and Xerox copies will usually have subtle scale differences between the x and y coordinates because the optical scales are not perfectly matched to the scanner movement scale. It is therefore imperative that all such products are individually georeferenced to re-establish the correct scale factors. That means that a sufficient number of control points are identified with respect to some geographic coordinate system.

The georegistration of topographic maps and orthophotoquads can be accomplished by telling the software the location of coordinate tic marks (+ signs) on a map. The initial setup for georegistration is important. The proper coordinate system needs to be specified, though it may be possible, for example, to enter coordinates (and view them in a table) in the latitude/longitude system but save them in the UTM system. The proper Datum and Geoid need to be specified. Topographic quadrangles are typically in the NAD1927 Datum with Clark 1866 Geoid. Properly made maps should have such information in the margins. There are display projection choices with various mathematical complexities: affine, plane projective, bilinear, polynomial, and piecewise versions. They dictate how an image is warped. The cursor is typically used to place a cross hair at a tic mark, with fine adjustments being made by keyboard arrow keys until the overlap is nearly perfect. In Fig. 130 the location is marked with a red symbol and labeled with a number. In the accompanying table in Fig. 131 is a list of the 16 coordinates of the tic marks.

##	Column	Line	Latitude	Longitude	Residual	(n)
1	172.12	162.50	N 47 00 00.0	W 119 30 00.0	5.926

15	1729.53	156.61	N 47 00 00.0	W 119 25 00.0	2.897	
16	951.39	159.96	N 47 00 00.0	W 119 27 30.0	4.027	

Fig. 130. Georegistration of a topo at tic marks. Fig. 131. A table of Georegistration numbers for a full quad.

The right column contains a list of residuals. That shows the calculated error associated with each location. Such errors should be minimized. Sometimes that can be done by choosing a different display projection choice. In this case, switching from the plane projective system to one of the polynomial powers can reduce these residuals to mostly less than 1 meter. Otherwise each point can be checked and adjusted, starting with the one with the largest error. The example used latitude/longitude tic marks. Alternatively

the UTM grid intersections on the topographic map could have been used, such as that in the lower left corner of the Fig. 130 example.

For fine resolution work a topographic map seldom has enough features that can be used as control points for an aerial photo or video image. Sometimes a coarse resolution aerial photo needs to be used as an intermediate georeference standard. Points in common between the aerial photo (left side, Fig. 132) are paired with the same features in the topographic map (right side, Fig. 132). After the residuals are minimized by appropriate adjustments or deletions of bad points, the software creates the proper georeference for the intermediate aerial photo. Ideally, a digital orthophoto quarterquad will be available, with 1 meter pixels, to serve as a reference image. Its georeference will be provided, eliminating the need for the previous two steps and providing a superior resolution. Then common objects like trees, rocks, road intersections, buildings, etc., can serve as georeference points, as illustrated in Fig. 133 (colored aerial photo on left, older B&W digital orthophoto on right). In addition to providing the locations of all positions in an image, the georeference process establishes the scales (meters per pixel) in the x and y (or column and line) directions for the image. Those scales may differ, particularly in rugged terrain.

Fig. 132. Tie points used to georeference an aerial image, using a topographic map as reference.

Fig. 133. Tie points used to georeference an aerial image, using an orthophoto as reference.

7. Photogrammetry

Photogrammetry, as defined by the American Society for Photogrammetry and Remote Sensing (ASPRS), is the art, science, and technology of obtaining reliable information about physical objects and the environment through processes of recording, measuring,

and interpreting photographic images and patterns of recorded radiant electromagnetic energy and other phenomena.

Originally the science was applied to analyzing photographs, either ground based or obtained using an airborne platform such as a balloon, blimp or piloted aircraft. In recent years photogrammetric methods and analysis have extended into fields such as Light Detection and Ranging (LIDAR) and digital imagery, and the airborne platforms now include un-manned aerial vehicles (UAV's) and satellites. However, the principal data source for photogrammetric analysis continues to be film based photographs.

Reclamation primarily uses photogrammetric methods, analysis, and products in the forms of aerial photography, orthophotography, digital elevation data (DEM, DTM, TIN, contours, cross-sections, etc.), topographic maps, and photographic interpretation (PI). Aerial photography, taken with a calibrated large-format (9"x9"), metric aerial survey mapping camera is usually of primary data source. In the past couple of years, larger format digital aerial cameras/sensors (Z/I DMC, Leica ADS40) have been developed, purchased, and are in use by several large North American mapping companies. On occasion Reclamation has a need to use ground based terrestrial or close-range photogrammetric methods to meet special project requirements. Close-range photogrammetry, defined as having a 300-meters or less object-to-camera distance, is based on the same scientific principles and similar data needs as the more familiar aerial based photogrammetry.

Aerial photography and photogrammetric methods have many applications within Reclamation, including compilation and production of many types of maps and digital data; crop maps, wetland maps, land use and management, infrastructure, vegetation, irrigation components/networks, riparian vegetation, geologic studies, geomorphology/sediment transport, hydraulic models, wildlife and aquatic habitat, change detection, trespass, and trend analysis.

Photographs are taken from essentially a point location, using a lens that may add some radial distortion (more obviously seen in a fish-eye lens) with respect to the center of the image. Perspective from that point location makes objects that are vertically near the camera appear at a radially greater distance from the center of the photograph than objects farther away. A vertical object, such as a building, tree or pole, as viewed in aerial photography, will appear to lean back radially from the image center. The same applies to topographic differences; hilltops will similarly lean away from the image center. Therefore aerial photographs will not have its viewed objects in exactly the same relative positions as should appear on a map. A computationally intensive process is used to correct for the lens and terrain distortions to produce a special type of image known as an orthophotograph.

In the past stereo analysis of aerial photography required large manual machines and manual operation by the person viewing the imagery. Perhaps fifteen years ago software was written for mainframe computers to semi-automate the process. More recently, some PC and workstation software packages allow the semi-automated analysis of a pair of

stereo images. Sometimes the phrase “soft copy photogrammetry” is used. After some initial definitions for scale, orientation, geographic registrations, elevation ranges, and an assortment of tie points (same physical object in both images), the software generates a pair of “epipolar” images in which all elevation displacements are along an axis parallel to the line between the photo centers. Additional tie points are then added, especially along ridges, depressions, and slope changes. The software then uses an autocorrelation

Fig. 135. A hill and valley stereo pair as left = red, right = cyan.

technique to identify other points that are the same object in both images, then convert their positional differences (parallax), parallel to the line between the centers of the two images, into elevation values. The result is a digital elevation model (DEM), expressing the elevation everywhere across a scene within the overlap of the two stereo images. The elevation data can be contoured to provide a map representation. In a related process, if the digital elevation data are known, the picture can be warped to remove distortions caused by elevational differences. The resulting product is known as a digital orthophoto. Quadrangle versions are known as DOQ and DOQQ. They are excellent products for georeferencing aerial and satellite imagery. As an example, Fig. 134 shows a small stereo pair of a badland hilltop and adjacent stream valley with the left image on the left and right while the right image is in the center. The left and center views can be

used with a stereoscope or viewed directly by people who can see straight-on stereo. The center and right views are for people who can do cross-eyed stereo viewing. Another version in Fig. 135 shows a superimposed, colored version with red for the left image and cyan for the right. When viewed through anaglyph glasses with red over the left eye and cyan over the right, the topography will appear in 3-dimensions. However, if the colored lenses are reversed, hills will appear as pits and valleys as ridges.

Fig. 134. A hill and valley stereo pair as left-right-left.

After the DEM has been generated by the software, it is usually good to run a median filter over the result to remove some of the noise and small blemishes. For comparison, the topographic map, with 20 foot contours was resampled as Fig. 136 to the extents of the stereo view. The DEM derived from the stereo pair is colorized in Fig. 137 at 1 meter vertical resolution, with the dark bands at 5 meter intervals. There is much more detail in the stereo-derived DEM, much from rocks and grass tufts, but there are also some blemishes caused by shadows and other things that confused the autocorrelation process.

Fig. 136. Topographic map with 20' contours.

Fig. 137. Colorized DEM derived from stereo pair.

An example of the value of orthophotographic rectification is shown by a view of the Interstate-70 cut through the hogback west of Denver. The aerial photograph was taken

Fig. 138. Aerial photo of I-70 warped to an orthophoto.

at a relatively low altitude and therefore experienced strong radial displacements of high topography. The scene was georeferenced to an orthophoto produced by a combination of IFSAR (interference synthetic aperture radar) derived topography and an IKONOS satellite image. The aerial photo was then warped by software designed to produce an orthophoto from an aerial photograph and a DEM (digital elevation model). The result was superimposed on top of the IKONOS image. It is useful to watch for mis-matches along the edges of the warped photograph. They indicate the quality of the software adjustments. It is seen in Fig. 138 that the picture edges are

greatly distorted by a reversal of the radial stretching in the original view. The amount of change in this image of rugged topography shows the need for orthophotographic corrections of an aerial image.

A scanner uses the forward motion of the aerial or satellite platform to assemble a series of cross-track image lines into a 2-dimensional picture. The instantaneous view is only along a narrow slit perpendicular to the flight direction. All elevation distortions are perpendicular to the flight line. Higher things lean back away from the flight line. Elevations can be derived only from parallel passes, not imagery from a single pass, and then from a more specialized software algorithm.

Some satellites are able to take off-nadir views intentionally. Such images can be used as stereo pairs to derive elevations of the landscape. The early SPOT satellites took their off-nadir views perpendicular to the orbital path, requiring that the pairs were taken on different orbits and days. The ASTER camera on the Terra satellite routinely takes a nadir view and a backwards view (along orbital path) in the NIR band 3, designated 3N (nadir) and 3B (backwards). The newest generation of high-resolution satellites, IKONOS (Space Imaging), Orbview-3 (OrbImage), and QuickBird (Digital Globe) have the capability to obtain 1-meter or better spatial resolution images in the panchromatic wavelength band. These images, properly manipulated, are suitable for many applications including orthophotography and digital elevation data extraction. They can acquire imagery at any angle with respect to the vertical and orbital path. Off-nadir and scanner geometries require special software algorithms for deriving elevation models.

Reclamation currently has three aerial photography and mapping services IDIQ contracts in place; UC-Salt Lake City (Bureau wide), GP-Billings, and MP-Sacramento. You must be able to effectively communicate your data requirements to the Reclamation Contracting Officers Representative (COR/COTR) and in turn the photogrammetric mapping contractor to ensure success for your mapping project. Reclamation offices in Denver, Phoenix, and Sacramento also have persons knowledgeable in photogrammetry and photogrammetric workstations. Depending on the size and needs of your project you may want to consult with Reclamation people and tap into their experience.

Proper planning is essential to the success of any photogrammetric mapping project. One of the first things that needs to be determined are your data requirements, including the accuracy needed. Data requirements include being able to accurately describe or delineate on a map where you want your photogrammetric data collected and when. Higher accuracy or resolution data does cost more than lower accuracy/resolution data.

A typical scope of work (SOW) for photogrammetric data acquisition would include things such as; project area map, scale of aerial photography needed, film type (panchromatic/BW, color, color infrared), timing of aerial photo acquisition, targeted map/data accuracy, ground control and/or airborne GPS control needed (accuracy driven), contact prints-diapositives-enlargements needed, digital orthophotographs needed (w/pixel size stated), elevation data needs (DEM/DTM, mass points/breaklines, spot elevations, contours, cross-sections, hydro-corrected DEM, etc.), planimetric

features to collect (scale driven) such as roads, curbs, hydrology, buildings, infrastructure, vegetation, etc., file formats and sizes, flight line maps (digital & hardcopy), are any hardcopy map plots needed or just the digital data, delivery dates, etc.

A photogrammetric workflow process should include:

1. Define area to be mapped, data and mapping products needed.
2. Prepare a detailed scope of work.
3. Plan aerial photography and control (ground and/or airborne GPS) acquisition.
4. Aerotriangulation
5. Digital elevation (terrain) model (DEM, DTM) data collection.
6. Digital orthophotographs; radiometric correction, editing, mosaic, format, image compression (if needed).
7. Triangular irregular networks (TIN) and contours.
8. Planimetric feature collection.
9. Edit contours and planimetric features.
10. Map graphics and data file tiling (if needed).
11. Data file formatting; image files, AutoCAD files for engineering, ArcInfo for GIS, etc.
12. Map plots on paper or film; edit, legends, size/scale, index map, etc.
13. Production of FGDC compliant metadata.

The primary pieces of information needed for a photogrammetric mapping project are an image source (aerial photographic film or digital imagery), ground control and/or airborne GPS coordinate data, and a camera calibration report. If these pieces have been properly collected for your project area you can then use photogrammetric equipment and techniques to extract and produce various types of data.

Map accuracy standards

The primary accuracy standards in use today are the National Map Accuracy Standard (NMAS) initially developed in 1947 and expanded upon during the last decade by subcommittees of the Federal Geographic Data Committee (FGDC), and the ASPRS Accuracy Standards for Large-Scale Maps (1990) class 1, class 2, and class 3. The ASPRS Class 1 standards are more rigorous (costly) and contain more definitive statistical map testing criteria, lower classifications will be more economical, with decreased accuracy.

NMAS Horizontal accuracy: NMAS states that for maps of publication scales larger than 1:20,000, not more than 10-percent of points tested shall be in error more than 1/30th of an inch, measured on the publication scale; for maps of publication scales of 1:20,000 or smaller, 1/50th of an inch. These limits of accuracy apply only to well-defined points (easily visible or recoverable on the ground). For example; a 1:24,000 scale map should have a horizontal accuracy of 40-feet (1/50th inch), and a 1:12,000 scale map should have a horizontal accuracy of 33.3 feet (1/30th inch).

NMAS vertical accuracy: As applied to contour maps at all publication scales, shall be such that not more than 10-percent of the elevations tested shall be in error more than one-half the contour interval; i.e. a 10-foot contour interval map should be within 5-feet vertically.

Table 1. ASPRS Class 1: Planimetric Feature Accuracy (X or Y coordinate in feet, for well defined points. (From ASPRS and COE)

Map Scale 1"= x feet	Ratio feet/foot	Limiting RMSE in X or Y (feet)
40	1:480	0.4
50	1:600	0.5
100	1:1200	1.0
200	1:2400	2.0
300	1:3600	3.0
400	1:4800	4.0
500	1:6000	5.0
600	1:7200	6.0
800	1:9600	8.0
1000	1:12,000	10.0
1667	1:20,000	16.7

Target contour Interval (feet)	Topographic Feature Points	Spot Elevation Points
1	0.33	0.17
2	0.67	.33
3	1.0	.50
4	1.33	0.67
5	1.67	0.83
10	3.33	1.67

Table 2. ASPRS Class 1: Elevation Accuracy for Well-Defined Points. (From ASPRS and COE). ASPRS Limiting RMSE in feet

Keep in mind that Reclamation IDIQ mapping contractors have been selected in part due to their rigorous quality control (QC) program. The testing of map accuracy can be costly and time consuming, Reclamation, as with most government entities, relies heavily on the contractors QC program and procedures to check for and catch mistakes. A photogrammetric mapping project should not be an adversarial process, if planned, carried out, and checked properly you will end up with a good project. The vast majority of contractors want to produce good and accurate products, and depend on customers to return with new work. If their reputation suffers due to sloppy or careless work their workload usually suffers too.

Final Map Scale	Pixel Size (ground units) in feet
1"= 50 feet (1:600)	0.25
1"= 100 feet (1:1200)	0.50
1"= 200 feet (1:2400)	1.0
1"= 400 feet (1:4800)	2.0

Table 3. Recommended Pixel Size for Selected Orthophotograph Map Scales:

8. Digital Elevation Models

Digital elevation models of various resolutions and qualities are available for free or purchase from the USGS. The oldest series were derived from 1:250,000 scale topographic maps by the Defense Mapping Agency (DMA) decades ago. They are available in 30 arc-second and 3 arc-second resolution, meaning that data points are every 30 or 3 seconds of arc in latitude/longitude coordinates. This set is continued in the global GTOPO30 DEM for the 30 arc-second series. The user should be aware of flaws in these data. The data do not always match the real topography. Sometimes the georegistration of the data is offset. Some elevations seem quantized at elevations like 200 ft, which is the contour interval on many of the maps used in deriving the DEM. A newer series is the 30 meter DEMs derived from 7.5 minute topographic map contours. More recently, DEMs have been developed as byproducts of digital orthophotos.

In 2000 the Space Shuttle used C and X band SAR radar technology to create a DEM of the entire U.S.A. at 1 arc-second resolution. Since 2003, it can be ordered in Arc-GRID format at <http://srtm.usgs.gov/data/obtainingdata.html>. The Shuttle Radar Topography Mission (SRTM) is a joint project between the National Imagery and Mapping Agency (NIMA) and the National Aeronautics and Space Administration (NASA). For the rest of the world the project produced digital topographic data for 80% of the Earth's land

Fig. 139. The DMA DEM for the Ohio region showing flaws.

surface (all land areas between 60 north and 56 south latitude), with data points located every 3-arc second (approximately 90 meters) on a latitude/longitude grid. The absolute vertical accuracy of the elevation data is 16 meters (at 90% confidence). Perhaps a more convenient source in GeoTIFF format is from the University of Maryland site, <http://glcfapp.umi.acs.umd.edu:8080/esdi/index.jsp>, which also has free Landsat and some ASTER data.

To illustrate some of the problems in the older data set, a subset of the 30 arc-second data in the Ohio River valley, N 37° to 41° 20', W 80° to 85° is displayed in Fig. 139. Dark tones are lowlands and bright tones are highlands in this normalized contrast rendition. The Ohio River extends from the upper right to the center left. Across this scene the amount of detail varies significantly. The southern portions have much fine detail. The northwest is greatly smoothed, mostly by the continental Ice Age glaciers. To the right of the center there is a 1-degree square within which are large flat areas, looking very artificial.

For the northwest portion of that DEM data set the software was used to create a solar shading, as if the sun were in the northeast (45° azimuth) at 50° above the horizon (an impossible location). The shaded diagram in Fig. 140, with normalized contrast, is

Fig. 140. A shaded relief of the Ohio DEM.

annotated with red marks at the 1° latitude/longitude positions. Notice that there are some edges visible between the 1° squares, indicating a mismatch of elevations. The flat, plateau-like data area is in the lower right portion of this view. Such flaws create severe problems for spatial analysts.

For comparison, the second shaded view in Fig. 141 uses data from the Shuttle mission, subsampled to the same resolution. The flaws are missing and the detail is better. The smooth areas in the northwest now clearly show a set of terminal moraines from the Ice Age glaciers.

Fig. 141. A shaded relief of the Ohio DEM using Shuttle radar data.

When a solar shading image is created, the software must also derive slope and aspect images. Areas in the slope diagram in Fig. 142 with a value of zero are colored red. This highlights the DEM problem areas. Apart from such flaws, slope images are

best shown with logarithmic contrast. Steep slopes will be bright. The general texture of slope images is one of a pile of spaghetti. Some lines, as in the upper left, seem artificial where there is a jump in the elevation because of analytical resolution in creating the DEM.

Fig. 142. Slope version of DEM, white are steep slopes

Fig. 143. Aspect version of the DEM.

Aspect images have a different visual texture, that of a metallic surface, shown in Fig. 143. Values of 0 and 240 represent a slope to the north. 60 is eastern, 120 is southern, and 180 is western. Intermediate aspects are proportionally distributed. The white areas in this image are where no aspect could be determined because of zero slope over distances greater than the size of the window within which the aspect is calculated.

Viewshed

DEM data can be used for calculating viewsheds from a particular location. A DEM data set from the southeastern U.S.A. (without serious flaws) has been selected for illustration. (N 32° 40' to 37°, W 80° to 85°). In this solar-shaded view of Fig. 144 the southern

Fig. 144. Shaded relief in southern Appalachians and Piedmont.

Fig. 145. Viewshed (red) from a mountain peak, sees the Piedmont but not into the mountains.

Appalachian Mountains are prominent, as well as the Piedmont. A particular high point was selected on the southeast side of the range. The viewshed program was instructed to show the terrain as viewed from 3 meters above the peak. The flat-earth solution was computed rather than one simulating earth curvature. The viewpoint is at the green crosshair and circle. In Fig. 145 the terrain in view is colored red on the DEM. The view of the lowlands is excellent, being affected only by local topography. The view does not penetrate into the mountains to any significant extent.

The viewshed program is also useful for crudely predicting FM radio propagation, where a signal might reach the ground. In practice, the computation really needs to use an Earth radius of 4/3 the actual Earth radius to simulate the refraction of radio waves in the atmosphere. It is only appropriate for FM transmissions, which are generally line-of-sight, not for AM or short-wave radio which interact with the ionosphere.

Watershed

The same Piedmont DEM was used in the watershed routine, originally written about 1990 at the USGS EROS Data Center, Sioux Falls, SD, and later adapted to numerous

Fig. 146. Water flow accumulation result from a watershed program, with basin boundaries.

software packages. The routine fills in any closed depressions in the DEM, then computes aspects for flow directions. For each pixel it determines the number of pixels upslope, thereby computing an accumulation image. Natural watershed boundaries and flow channels are determined. The routine allows the analyst to nominate one or more “pour points” for the determination of the upstream watershed from that location.

This illustration in Fig. 146 is of the flow accumulations (logarithmic contrast) as white lines on a black background, with

gold lines being the default watershed boundaries determined from which large channels intersect the edge of the view. Many other products could also be displayed.

Vegetation Gradients

Fig. 147. Landsat view of Wind River Range, Wyoming.

DEMs can also be used as a component in 2-D histograms. A nearly entire Landsat TM scene (red band 3) of the Wind River Range in Wyoming was selected. The elevations of the same area, from the Shuttle SRTM data, were rescaled to an 8-bit range by subtracting an offset and dividing by 12. The scene in Fig. 147 shows bright lowlands with dark irrigated fields. The

highlands are snow covered in this early July scene. In between the slopes are covered with dark conifer trees.

Fig. 148. A 2-D histogram of scene brightness (X-axis) and elevation (Y-axis).

A 2-D histogram of the scene was calculated for Fig. 148. The bottom graph shows the distribution of digital numbers for the red raster, with dark to the left and bright to the right. The left graph shows the distributions of rescaled elevations. The lowest elevations are from the upper right corner, the lower peak from the eastern lowlands, and the main peak is from the southern lowlands. In the colored portion the central green patch with red core represents the southern lowlands, the lower small green dot the eastern lowlands, and the left vertical green patch with red core the conifer covered mountain areas. The snow patches are at the upper right edge, showing saturated brightness. Elevation control of band 3 brightness is strong in this scene.

9. Geographic Information Systems

A Geographic Information System (GIS) is a computer program that organizes data according to their geographic relationships. Originally the term tended to be restricted to a particular software brand and to its descriptions of the boundaries of regions with common properties (fields, roads, rivers, land cover types, etc.). The latest software versions have greatly expanded their capabilities, making the GIS term cover many more techniques.

Rasters

A GIS will usually contain an image processing system that manipulates rasters (2-dimensional imagery). Such imagery can be used as background upon which GIS analyses are overlaid. Rasters are often the source upon which vector (points, lines, areas) interpretations are generated through the process of digitization or direct raster-to-vector conversion.

Fig. 149. A view of Winchester Wasteway, illustrating sketched vector features.

Vectors

A vector object is a collection of points, line segments, polygons, and nodes and annotation, illustrated in Fig. 149. Line segments (red) connect points, though some points (cyan) can be left as isolated points to identify locations of particular objects. A set of line segments that encloses an area is called a polygon, which is normally very irregular in shape. Line segments intersect (T, X, or other shape intersection) at a node (yellow). Line segments can end at a dangling node (green). Polygons can be islands within other polygons. Annotation, or Labels, help interpretation. These vector objects can be assigned any desired color and drawing style. Polygons can be filled with solid colors or patterns and be shown with or without border lines.

Vectors can be generated directly from paper (or other physical medium) maps and imagery by the process of digitization. The paper is fastened to a digitizing tablet. The coordinates (x,y pairs) are read electronically as a cross-hair device is moved over the features of interest. The same can be accomplished on a computer screen by “heads-up” digitizing. The map or imagery is scanned and displayed on the computer screen as a raster; the cursor is moved over the features of interest to get the coordinate pairs. Software techniques exist to convert lines in raster imagery into vector lines, as shown later for contour following.

Fig. 150. Vector generated from automated classification.

Similarly, boundaries of solid colors in a raster (created by a classification process) can be converted to polygons. In Fig. 150 a raster was created from Landsat data by a partition process. The white areas are clouds and the cyan are snow on the ground (tan). Nodes are dark. The vector polygons were generated at the pixel edges, as shown by the square-stepped borders. The polygons were automatically assigned a numerical classification code identical to the code represented by the colors.

Fig. 151. Vector polygon classification of plant types.

Lines can be used to represent roads, railroads, trails, streams, political boundaries, field boundaries, etc. Polygons can be labeled according to the contents of their interiors. Such can be soil types, land cover, water rights, and many other categories. The Fig. 151 example is a plant classification created by visually examining a scene in stereo aerial imagery, hand-drawing boundaries on a basemap image and assigning the classifications to the resulting polygons. Each plant class is assigned its own color code. Here blue is unclassified land and water, yellow is the reed Phragmites, green is cattails and bulrushes, magenta is flowering purple loosestrife, brown is unhealthy purple loosestrife, and tan is dead purple loosestrife.

loosestrife, all along the Winchester Wasteway in Washington.

Polygons from different data layers (like elevation zones, soil types, land cover, population density, endangered species locations) can be overlapped to show relationships between the different data layers, possibly generating additional categories for classification. Buffer zones at fixed distances from other objects (points, lines) can be created by the software.

Vector sets generally take less storage space than rasters and are faster to analyze. However, they cannot contain the fine image detail of rasters. They are best for generalizing properties under consideration. Vector objects can have data base and text objects assigned to them, whereby the data associated with some vector object can be viewed at will.

The process of generating vector data, either by hand entries (digitizing) or by conversion from raster data, will usually generate errors. Hand vibrations and pixel edges cause wavy line segments which may need smoothing. Line intersections may have overshoots to be removed, or the lines may not connect at all, requiring “snapping” to form a connection at a “node”. A merger of vector data from two sources may have lines that should be the same. However, irregularities in the line data during a merger process cause an artificial creation of tiny polygons along what should be a single line. Such artifacts need to be removed. Vector cleanup is mandatory before analysis can properly begin. For illustration, some vector data were automatically generated from a contour map.

In Fig. 152 the numbers generated junk lines that need to be removed. These are examples of dangling lines. They can be marked for deletion (shown in red) or possibly removed by specifying a short length threshold. Other lines that are not contours also need to be removed. In Fig. 153 there is a small triangular polygon that should not be there. Such artifacts could be removed. In Fig. 154 the errors were generated by contours that were close together. Fig. 155 shows some additional lines (green) were edited manually, while the red lines were marked for deletion. The excess nodes (blue) were then removed.

Fig. 152. Dangling line.

Fig. 153. Bubble artifact.

Fig. 154. Multiple bubbles.

Fig. 155. Hand Scketching

Databases can be attached to vector elements. By touching an element with the cursor the data base information for that element is brought into view. Sometimes values in the database can be used to affect the size of vector symbols.

Though vector sets are normally 2-dimensional, 3-dimensional vectors can be created by assigning elevations to all components. A 3-D representation of a topographic map has the contours with assigned elevations (no contours can cross if their elevations differ) and possibly some individual points (bench markers). Such 3-D contours can be used to generate a surface raster which is a digital elevation model (DEM). The three major steps are shown in Fig. 156

CAD

Vector sets without precise topological rules can be expressed as CAD (computer aided design) objects. Otherwise they are similar.

Fig. 156. Steps in making a DEM from a topographic map.

TIN

A triangular irregular network (TIN) is a series of triangles, the nodes of which express some data quantity, such as elevation of a surface. Within each triangle the data are assumed to vary linearly with direction. Where changes are more rapid and non-linear, the triangles are smaller and closely packed. In regions that are generally flat or with a constant magnitude and direction of slope, the triangles are large and sparse. A TIN representation of a variable surface usually takes less data storage space than a DEM and provides computational advantages when generating 3-dimensional perspective surfaces.

Data Bases

Data Bases (DB) allow an organization of data of various types. Software can form an attachment of DB elements to vector objects so that properties associated with the vector objects can be read or interrogated. Sometimes the data base values can be used to control the plotted appearance of the vector objects, such as symbol size or orientation. Queries can be made to quantify and map particular DB values. Data Bases, such as Dbase, Oracle, and Informix, could be easily linked to a GIS. This creates more value for storing, archiving, and analyzing data sets.

Conversions

Rasters can be converted to vectors and CAD. Vectors and CAD can be converted to rasters. DEMs and TINs expressing elevation can be converted to the other type.

Changes

There are many applications in which documentation of changes is of greatest value. This can be a time series of remote sensing and/or GIS data layers. It can be a comparison of conditions before and after some significant event. Remote sensing

products from satellites showed themselves particularly valuable in documenting the extents of damage following the Asian tsunami of late December 2004 and of Hurricane Katrina in southern U.S.A in late August 2005. A small segment of damage in Biloxi, Mississippi, is shown in Fig. 157. The upper half shows a “before” view from the IKONOS satellite operated by SpaceImaging. The lower half is the same view after passage of the hurricane when cloud-free skies allowed viewing from the satellite. At the right side, notice the destruction of the road causeways. At the left side, notice the movements of the casinos to onshore positions. Trees and houses were destroyed in most locations and their debris piled and scattered. Large buildings, with stronger construction standards, remained intact. In other cities all buildings and vegetation within several city blocks of the shoreline were scoured totally, leaving only remnants of the foundations. The same change detection techniques are applicable to other, lesser disasters.

Fig. 157. Before and after IKONOS views of hurricane Katrina damage at Biloxi, Mississippi.

10. Applications

Remote sensing data analyses can be valuable in themselves or as components for a geographic information system. Data in use by GIS software can be used to model relationships between variables and create new variables. The model might show the relationship of backwater areas for various river flow intensities. It might show the progress of a flood along a river corridor. It might show the discharge of a watershed in response to radar-detected precipitation within the watershed. A model might predict locations and extents of habitats required by an endangered species. A list of applications could be lengthy, as shown by Part II of projects already completed.

GIS analyses involve many more topics that are beyond the scope of this report. Here are some of them: Geographic analysis: a. Queries; b. Cartographic analysis; c. Buffering; d. Map algebra; e. Spatial analysis; f. 3-D analysis; g. Modeling techniques; h. Network analysis; i. Charts and reports. Geostatistics and Spatial Analysis: a. Software packages strengths and weaknesses; b. Sampling techniques; c. Descriptive statistics; d. Hypothesis testing - parametric and nonparametric tests; e. Analysis of variance: one way, two way, n-way; f. Bi-variate and multi-variate correlation and regression; g. Principal components analysis; h. Factor analysis; i. Cluster analysis; j. Discriminant analysis; k. Surface modeling techniques: kriging, inverse distance, triangular irregular networks, trend surface analysis; l. Network analytics. Accuracy Assessment: thematic, positional. Metadata: formal descriptions of data. Project Planning: a. Collaboration; b. Scoping; c. Interim and final reports; d. System deployment.

Contact the Remote Sensing and Geographic Information Group (D-8260; phone (303) 445-2267) to see if there are technologies available and appropriate for projects of special interest to your own group.

II. Overview of Usage Within the Bureau of Reclamation

The Remote Sensing and Geographic Information Group (D-8260) of the Bureau of Reclamation has several decades (since 1975) of experience in both research and applications. An appropriate technology is selected for each project to accomplish particular goals within the restraints of available time and budgets. We have encouraged the use of RS and GIS within the regional offices, so that local analysts can address local topics.

There are numerous commercial software products available. The Denver Office uses ESRI (ArcGIS, ArcView, etc.), ERDAS (Imagine), MicroImages (TNTmips), and Research Systems (ENVI) software to accomplish the project and research work. Each system has its own characteristics and specialties, but most capabilities overlap. Our workers tend to specialize in one particular brand of software. Data from each software

can usually be imported and exported in formats of the other brands, enabling the outputs to be in whatever format a client desires.

Supporting tools in our analyses include digitizing tablets, stereoscopes, light tables, printers, flat-bed scanners, and video capture equipment. Computer terminals are networked, allowing easy transfers between computers and servers. Internet access allows rapid download of data available from public sources.

Reclamation Project Examples

The following listing is for projects conducted by the team at the Denver Office since 1975. Regional offices have conducted studies of similar nature. These are listed to give inspiration about the range of possible projects and appropriate technologies. (Many of these could be classified into finer groups and lumped, naming the geographic regions in which a technique was applied.)

CIR photography for vegetative analysis along Rio Grande.

- Aerial imagery analysis for vegetative associations of Spring Canyon and Rifle Range Pumped Storage Survey sites, Lower Colorado region.
- Mapping of vegetative associations at Whipple Wash Pumped Storage site, Lower Colorado.
- Aerial photographic study of Ochoco Dam and Reservoir area, Oregon.
- Land cover analysis for the Republican/Solomon Rivers Water Management Study, Kansas/Nebraska.
- Photointerpretation for wildlife mitigation, New Rockford Canal right of way, Garrison Diversion Unit, Dakotas.
- Aerial photo studies of Clark Canyon Dam and Reservoir area, Montana; Hagmmaier Pond Dam South, Calif.; Tufa Stone Dam, Arizona.
- Land cover analysis and inventory of Tularosa Basin, NM.
- Mapping of Garrison area (Sand Lake, Dakota Lake, Hyatt Slough, Arrowhead Lake), National Wildlife Refuge Monitoring Program.
- Evaluation of riparian vegetation trends in the Grand Canyon using multitemporal remote sensing techniques.
- Post construction analysis at Calamus Dam, North Loup, Upper Missouri Basin.
- Determining impacted wildlife resources in the Grand Valley, CO, by remote sensing.
- Land cover mapping and analysis for Lower Gunnison Basin Unit, North Fork area, CO.
- Aerial photographic documentation of perennial vegetation changes near Granite Reef and Salt Gila Aqueducts, AZ.
- Vegetation identification and mapping for Gila River Indian Reservation, AZ.
- Photo interpretation along Snake River, Minidoka Project, Jackson Lake Dam.
- Vegetation mapping for All American Canal, Calif.

- Use of RS and GIS for estimation of irrigation water use in the Upper Gunnison River Basin of Colorado.
- Use of satellite RS and GIS for estimation of irrigated land acreage in the Newlands Project Area, NV.
- Baker Valley Irrigation District GIS data base and mapping.
- Use of aerial photography for vegetation monitoring along Heyden-Rhodes Aqueduct.
- Use of oblique slides with PC image processing system for Big Horn Sheep habitat analysis, Waterton Canyon, CO.
- Land use and land cover mapping at American Falls Reservoir, PN region.
- Evaluation of wetland changes on Klamath Lake with multitemporal remote sensing.
- Black Sands Area study for land cover trend analysis.
- Pecos River habitat quantification using aerial photography and videography.
- Wetland and riparian mapping along La Plata River, CO.
- Blunt Reservoir, Pierre Canal wetland and wildlife habitat mapping.
- Rio Grande land use inventory.
- Vegetative assemblage mapping of the Nueces River Delta, Texas.
- Using aerial photography (1:5000 scale, natural color positive transparencies in stereo), hyperspectral scanner, and IKONOS satellite imagery to map invasive noxious weed infestations (purple loosestrife, leafy spurge) and biocontrol effectiveness at the Winchester Wasteway, Washington and in the areas near Denver. The latter includes the Spring Creek and Buffalo Creek fire swath areas infested with leafy spurge, for the Forest Service.
- Inventory of wetlands and riparian communities for Animas/Laplata, CO.
- Mapping of riparian vegetation of the Lower Colorado River from Davis Dam to the international border, CA/AZ.
- Seedskadee NWR vegetation inventory.
- USGS - NPS vegetation mapping - Jewel Cave National Monument, SD.
- USGS - NPS vegetation mapping - Devils Tower National Monument, SD.
- USGS - NPS vegetation mapping - Mount Rushmore National Memorial, SD.
- USGS - NPS vegetation mapping - Wind Cave National Park, SD.
- USGS - NPS vegetation mapping - Badlands National Park, SD.
- USGS - NPS vegetation mapping - Theodore Roosevelt National Park, ND.
- Banks Lake and Conconully land use land covering maps.
- USFS Nebraska National Forest, Buffalo Gap National Grassland prairie dog colony mapping.
- Wetlands inventory and drained wetlands water storage capacity estimation for the St. Joe - Calio Coulee subbasin of the Greater Devils Lake Basin, ND.
- Cheyenne Bottoms Wildlife Management area, KS.
- Potholes Reservoir vegetated exposed bed.
- Vegetation mapping using vertical aerial videography along the San Luis Valley Project - Conveyance Channel Closed Basin Division - CO.
- Central Platte River land cover land use mapping, Nebraska.
- Ridgway State Park, CO, vegetation survey and mapping.

- Trinidad State Park, CO, vegetation survey and mapping.
- Rifle Falls and Rifle Gap State Parks vegetation survey and mapping.
- Yampa River Legacy State Park - Elkhead Reservoir vegetation mapping.
- Jemex Mountain, NM - habitat mapping project.
- Sunset Crater Volcano National Monument, AZ, vegetation mapping project.
- Lacreek National Wildlife Refuge, SD, vegetation mapping project.
- Ouray National Wildlife Refuge, UT, vegetation mapping project.
- Jasper Fire area vegetation mapping.
- Mapping of Route 285 for Colorado Dept. of Transportation.
- Knife River Indian Villages National Historic Site vegetation mapping project.
- Fort Union Trading Post National Historic Site vegetation mapping project.
- Zion National Park vegetation mapping.

Agricultural studies

- RS study of land use and irrigated crops in the Lower Sevier River Basin, Delta, Utah.
- Basin-wide remote sensing of irrigated lands in the Bear River Basin of Wyoming.
- Inventory of irrigated lands and reservoir surface areas in the Upper Green River Basin, Wyoming.
- Detailed sprinkler and land classification analysis, Lincoln Valley, Upper Missouri.
- Using Landsat TM imagery for cultivated lands identifications, James River/Oaks, ND.
- Land use, habitat mapping in Imperial Irrigation District, Calif.
- Using Landsat, SPOT and Indian IRS satellite data to map irrigated lands in Upper and Lower Colorado River basins.
- Mapping irrigated lands in the Yakima River Basin, WA, using digital satellite data.
- Mapping irrigated lands in the Clark Fork / Flathead River Basin of western Montana using digital satellite data.

Land Suitability studies

- Vegetation, salt, and soil inventory for McElmo Creek Salinity Control Unit, Upper Colorado.

Geologic mappings

- Lineament analysis at Brantley Dam, NM, using 1:24,000 scale imagery
- Using Landsat imagery of the Strawberry Reservoir area, Utah, for seismic hazard evaluation.
- Using Landsat imagery for lineament analysis of Stillwater Tunnel area, Utah.
- Photogeologic studies of landslide deposits at Lake Sherburne Dam, Montana; of Lake Darling Dam and Reservoir, North Dakota; of Ganado Dam area, Arizona; of Assayi Dam area, New Mexico; of Glendo Dam and Reservoir area, Wyoming; of El Vado Dam and Reservoir area, New Mexico.

- Using Landsat imagery for lineament analysis of Shell Creek Drainage, Wyoming.
- Demonstrated a technique for combining watershed analysis (using DEMs) with a map of Grand Canyon geologic formations, to be used by USGS to evaluate potential for each side canyon to produce debris flows.

Water studies (see also thermal and hyperspectral)

- A study of seepage along the Dry Gulch Canal, Uinta Basin Project.
- Using Landsat imagery to measure the area of Eagle Lakes, Columbia Basin.
- River bank recession analysis, Oroville-Tonasket Pumping Plant, Okanogan River, Pacific northwest region.
- An inventory of playa lakes, Llano Estacado.
- Water quality mapping of Flaming Gorge Reservoir, Wyoming.
- Multispectral Landsat imagery of chlorophyll-a in Flaming Gorge Reservoir, Wyoming.
- Water quality imagery of Bear Lake, Idaho/Utah.
- Using Landsat multi-date imagery of October, 1983, flood extents near Phoenix, AZ.
- Using airborne scanner imagery of Blue Mesa Reservoir, CO, for water quality patterns.
- Using Landsat data to quantify turbidity and chlorophyll content and measure surface temperature patterns in Lakes Havasu, Mead, Powell, Klamath; Flaming Gorge Reservoir.
- Remote sensing study for East Highline Canal seepage, Imperial Irrigation District, Calif.
- Using MAMS 12-channel scanner data for surface water quality patterns on Lake Pleasant, Arizona.
- Using remote sensing (aerial photography, videography) and GIS for backwater studies, sediment transport, channel characteristics along Green River, Utah, below Flaming Gorge Dam.
- Backwater habitat mapping for Colorado River in Grand Canyon.
- Use of SPOT satellite data for mapping chlorophyll on Lahontan Reservoir.
- Aerial photography documentation of changes and vegetation along Coachella Canal, Calif.
- Fontenelle Dam tailwater mapping.
- Remote sensing of San Juan River for habitat mapping for endangered fish.
- Routine monitoring of Green, Colorado, San Juan Rivers by aerial videography.
- Erosion mapping of Audubon Lake Island.
- Water quality studies on Hanks Marsh, Klamath Falls, OR.
- Using aerial video from helicopter flying about 100 ft above canal of Central Arizona Project to quantify and locate patches of aquatic weeds that hinder water transport, for measuring the effectiveness of biocontrol of weeds by grass carp.
- Using aerial video to map rapids and riffles along Yakima River.
- Limnological applications of multispectral remote sensing.
- High/Low flow studies of wetted area and river channels in the Rio Grande River.

- Using aerial photography (1:12,000) to map all man-made structures (dams, canals, channels, pumps, diversions, fish screens) related to water usage in the John Day River Basin, Oregon.
- Utility of GIS for the National Irrigation Water Quality Program in the Grand Valley.
- Green River waterline mapping at 10,900 cfs using airborne videography.

Dam Safety studies

- Clark Canyon Dam, MT, dam failure inundation study.
- Use of geospatial technology to automate dam breach inundation mapping and emergency management within Reclamation.
- Green River flooded bottomlands mapping for two flows.

Thermal studies

- Studies of geothermal sites at Susanville, Holtville.
- Thermal IR imagery at Meeker Dome for salinity control.
- Thermal IR imagery downstream of Theodore Roosevelt Dam.
- From pre-sunrise aircraft flight over the Platte River, Nebraska, to count the number of Sandhill Cranes on each island and sandbar before they moved into the fields to feed..
- Thermal IR imagery of Fontenelle Dam, Wyoming.
- Thermal IR imagery of the New Waddell Dam site, Arizona.
- Using FLIR system (thermal scanner and visible video) from helicopter below the canyon rims in the eastern Grand Canyon and the canyon of the Little Colorado River, to measure the temperatures of the rivers and backwaters and to identify warm springs, to locate favored habitats for endangered fish.
- Using a Daedalus scanner in the Grand Canyon and Little Colorado River to measure river and backwater temperatures.
- Using a Daedalus scanner along the lower Yakima River, Washington, to measure water temperatures in the Columbia and Yakima Rivers, backwaters, isolated ponds, and canals, especially comparing the temperatures of water entering the rivers with the river temperatures there.
- Using Landsat band 6 to measure surface temperature patterns in Lakes Mead, Powell, Klamath.

Hyperspectral studies

- Using ASDI Field Spectrometer to measure fine details of spectra of various rocks, minerals, soils, plants, flowers, Autumn colored leaves, sky, clouds, snow, and man-made substances, with a stress on invasive noxious weeds at various seasonal stages. The more than 4600 measurements are available on a CD or a web site for use by others as reference spectra.
- Using the Probe-1 (128 channels) scanner at the Winchester Wasteway, central Washington, to view a habitat of mixed sand dunes, wetlands and irrigated fields, examining in particular the effects of biocontrol beetles on purple loosestrife infestations, plus distributions of Phragmites (cane), bulrush, and cattails.

- Using the AVIRIS (224 channels) scanner for water quality studies at Klamath Lake, Oregon.

Social, Economical, and Demographic studies

- Numerous population at risk and economic impact studies for modeled dam breach flood zones for many of Reclamation's high and significant hazard dams.

EIS studies

- Garrison Diversion: Photointerpretation for Wildlife Mitigation on New Rockford Canal. 1982
- Remote Sensing for Sandhill Crane Roosting Habitat on the Platte River 1983
- Glen Canyon Environmental Studies, for the Biological Assessment : Evaluation of Riparian Trends in Grand Canyon 1986
- Biological Assessment for the operation of Flaming Gorge Dam, Mapping backwaters in the Green River 1987
- 1988- Platte River Studies mapping Channel Changes
- Environmental Assessment for Coachella Canals Wetland Mapping study 1989
- Refuge Monitoring for environmental Assessment on the James River in North and South Dakota 1990

A photograph of a person standing on the peak of a large, light-colored rock formation. The person is wearing a white tank top and dark shorts, and is holding a camera up to their eye, taking a picture. The background is a bright blue sky with scattered white clouds. The rock formation has a rough, textured surface with some shadows.

ACKNOWLEDGMENTS

I thank my colleagues within the National Operations Center–Division of Resource Services and other offices within BLM who have supported the use of photogrammetry in the Bureau. In addition, I especially thank my coworker, Tom Noble. Several years ago Tom began applying his knowledge of mathematics, surveying, and software programming to photogrammetry. The BLM and the use of close-range photogrammetry in general have greatly benefited from his efforts. I thank the following persons for their reviews of this manuscript:

ABSTRACT

Photogrammetry is the art and science of obtaining precise mathematical measurements and three-dimensional (3D) data from two or more photographs. The Bureau of Land Management has benefited from its in-house photogrammetric capabilities, support, and expertise for more than 20 years. This support includes creating unique and value-added digital datasets and serving as subject matter experts and contracting officer's representatives to obtain aerial photography and other types of 3D data. Traditionally, most people think of photogrammetry in the context of aerial photography. Photogrammetric techniques can be applied to virtually any source of imagery, whether it comes from 35-mm digital cameras or an earth-orbiting satellite. As long as the images are captured with stereoscopic overlap, one can derive accurate 3D data at a very wide range of scales.

The rapid evolution of digital cameras and increasing capabilities of computers and analytical software has dramatically expanded the variety of situations to which photogrammetry may be applied, while simultaneously decreasing the costs of acquisition, processing, and analysis. A variety of resource specialists (such as hydrologists, soil scientists, archaeologists, paleontologists, biologists, range conservationists, and engineers) can greatly benefit from 3D products derived from modern photogrammetric techniques. This is especially true in the field of ground-based or close-range photogrammetry. This document provides a general overview of photogrammetry, with separate sections focusing on traditional aerial photogrammetry and close-range photogrammetry. The appendices contain technical information on the equipment and suggested methods for capturing stereoscopic imagery. Their purpose is to assist field resource specialists in the successful completion of the imagery collection portion of a basic, close-range photogrammetry project.

INTRODUCTION

The United States Department of the Interior, Bureau of Land Management (BLM) is charged with managing almost 104 million ha (256 million acres) of surface land. This vast landscape includes some of the most ecologically and culturally diverse, scientifically important lands in Federal ownership. Documenting and evaluating the present condition—and in some instances, past condition—of its land is a critical part of the Bureau's mission. Not only do these condition data provide information on the health of the land and serve as a basis for future decision making, but they also provide a tool for determining the effectiveness of

present management practices. To most efficiently support the BLM's management effort, documentation methods that are quantifiable and repeatable are needed.

A tool for capturing present condition is photography. While visually enlightening, a single photograph is in many ways anecdotal and can be biased by the perceptions of the photographer (Mudge et al. 2006). However, photographs can be taken in such a way as to provide detailed and measurable three-dimensional (3D) data, thus providing a more robust dataset from which an analyst can derive quantifiable

information. The science and technology of this process is called photogrammetry (Appendix A). The basic requirement for photogrammetry is an overlapping pair of photographs taken to mimic the perspective centers of human stereoscopic vision. Photography, at virtually any scale (from a pair of images taken from an earth-orbiting satellite to extremely close-up images of a delicate biological soil crust), can be processed by using photogrammetric techniques. The resulting datasets integrate both corrected imagery and 3D surface data that can be viewed, manipulated, and measured by using GIS and other similar software.

Since the 1930s, most of the topographic and thematic maps produced in the United States have been made according to aerial photography and photogrammetric methods. Aerial photography, digital imagery, ground control survey data, and photogrammetry are the basic components for many of the maps and geographic information systems (GIS) data used by the BLM. For more than 20 years, the BLM has maintained some in-house photogrammetric capability with specialized expertise and equipment. This capability assists the Bureau in meeting its unique data needs (e.g., riparian boundary litigation) and by providing large-scale mapping products not available from other government agencies.

Within the last decade, advances in digital imagery and photogrammetric software, combined with lower equipment costs (Matthews et al. 2004), have enabled the use of photogrammetric methods over a wider range of applications, while at the same time reducing equipment costs and decreasing computing times, making the entire process more cost-effective. These advances have revolutionized close-range photogrammetry by removing many of the rigors of traditional aerial photogrammetry, thus moving stereoscopic image collection from the hands of the photogrammetric expert to those of field personnel.

A significant advantage of close-range photogrammetry is that images for a small project can be acquired with minimal field equipment and a small amount of training. Once taken, these images can be processed to a detailed, 3D grid of thousands of precise data points or archived and processed when needed to provide quantifiable measurements of condition. This can support long-term comparisons and provide a visual and metric dataset that cannot be achieved through any other method. Because accurate measurements can be made from the dataset, the resulting determinations are more defensible than simple anecdotal evidence (e.g., a single photo). In addition, these datasets can be more persuasive to both the internal and external audience, thus supporting better-informed conclusions.

In the past year, the 3D measuring and modeling software used to process close-range photographs has increased in its capability and ease of use and decreased in cost. Both traditional aerial and close-range photogrammetric processing are presently limited to BLM staff at the BLM National Operations Center (NOC) and the Alaska State Office. However, software and hardware innovations will continue to increase the accessibility of both stereoscopic processing and viewing, making photogrammetry more accessible within the BLM and providing a cost-effective, responsive, and quantifiable documentation and monitoring technique.

This report is intended to provide resource specialists with an overview of photogrammetry—both traditional aerial and close-range—and to provide examples of projects to which these technologies have been applied. In addition, the appendices contain the requirements of stereoscopic image capture, describe proper camera settings, and outline the basic procedure for field capture of images for a small, close-range project.

WHAT IS PHOTOGRAMMETRY?

Photogrammetry is the science behind the creation of almost every topographic map made since the 1930s. The human ability to perceive depth is the basis for the science (and technology) of photogrammetry. This ability to see in three dimensions is due to the offset in perspective centers between the left and the right eyes. Photographs taken to mimic this perspective shift are referred to as stereoscopic or stereo (meaning two). A stereo pair (or series) of images is taken from consecutive positions and overlap each other by at least 60%. Through the use of photogrammetry, highly detailed three-dimensional data can be derived from the two-dimensional photographs of a stereo pair.

The formal definition of photogrammetry is the art, science, and technology of obtaining reliable information about physical objects and the environment through the process of recording, measuring, and interpreting photographic images and patterns of electromagnetic radiant energy and other phenomena. In many instances, the use of photogrammetry can be more efficient, less labor-intensive, and more cost-effective than other types of field 3D data collection, resulting in products that have a level of detail, accuracy, range, and price that is difficult to match with other technologies (Birch 2006). As described previously, the main component necessary for a photogrammetric project is a series of overlapping stereoscopic images. The stereo images may be captured by a large variety of cameras at almost any height or platform (from tripod to earth-orbiting satellite).

Photogrammetry is informally divided into two basic categories according to the height of the platform—traditional (or aerial) and nontraditional (or close-range). Advances in commercially available and cost-effective photogrammetric software, high-resolution digital cameras, high-performance laptop computers, and unmanned aerial systems (UAS) have caused those categories to overlap in recent years. This document refers to the traditional process of acquiring and using large-format (e.g., 9 x 9 inch; Figure 1), vertical (film or digital) aerial images as aerial photogrammetry. Close range is used to refer to photographs with an object-to-camera distance of less than 300 m.

Figure 1. Example of a large-format (9 x 9-inch) vertical, natural-color, aerial photograph taken at a scale of 1:12,000. The area covered by the image is in north-central Wyoming. The Red Gulch Dinosaur Tracksite lies near the center of the image.

● AERIAL PHOTOGRAMMETRY

Aerial photogrammetry utilizes large-format imagery and ground coordinate information to effectively recreate the geometry of a portion of the earth in a virtual environment. In this virtual environment, reliable horizontal and vertical measurements can be made and recorded (or compiled) directly into a geospatial data file. Accurate measurements can be recorded from aerial photographic images, by using traditional methods, only when the following conditions are met: a) stereoscopic image pairs (two or more overlapping photographs) cover the object to be analyzed; b) accurate x , y , and z coordinates are known for at least three defined object points in the overlapping photographs; and c) a calibrated mapping or metric camera is used to take the photographs.

The compilation of planimetric features (such as roads and streams) and topographic information (such as digital terrain models [DTM] and topographic contours) from the photographic sources is accomplished through the use of digital stereoscopic instruments. Digital, or softcopy, photogrammetric workstations require specialized software and hardware for viewing a pair of stereo images. In this virtual environment, an experienced operator can link the images with the ground control to collect precise horizontal and vertical coordinates for a point, line, polygon, or surface. The photogrammetric workstation recreates the geometry of the field subject through a series of mathematical operations (Figure 2). These procedures require a high level of expertise and repetition to maintain the operator's skill. The softcopy instrument has analytical capabilities to a submillimeter level. Thus, high-accuracy ground control coordinate positions are needed to fully exploit the analytical capabilities of these instruments (Matthews et al. 2006).

Figure 2. Digital, or softcopy, photogrammetric workstations support stereoscopic viewing and measuring in a 3D environment, where an overlapping pair of images is viewed with special polarized glasses.

Aerial Photogrammetry Workflow

Most large-format aerial photography is acquired through commercial contractors and is available in hard copy (film) or digital formats. With the exception of the BLM Alaska State Office, the Bureau does not have the capability to acquire large-format aerial imagery without the assistance of a commercial contractor. In most instances, it is best to work through photogrammetric specialists, such as the staff of the Division of Resource Services (DRS) at the NOC to ensure that the technical and user requirements are met. It is important to begin planning for the acquisition of imagery early in the project. Many elements need to be considered to ensure that project requirements are met (e.g., size of the area, terrain, vegetation cover, sun angle, type of sensor, and product accuracy).

Generally, aerial acquisition is designed and planned according to the specifications needed to generate a particular product

with a specific scale and accuracy. The desired resolution dictates the height at which the contractor must fly to acquire the imagery. The following equation states the relation between scale and flying height of the aircraft (Hussain and Bethel 2004).

$$\text{scale} = \frac{\text{focal length}}{\text{flying height above terrain}}$$

For example; when film-based aerial photography is flown at a height of 305 m (1,000 feet) above mean terrain with a 153-mm (6-inch) focal length lens, the resulting photography has a scale of 1:2,000. With the resolving power of modern natural color film, the smallest object that can be detected is 5 cm. The distance of the sensor from the subject in commercial aerial photography is restricted by the altitude at which the plane can operate safely. In addition, the Federal Aviation Administration (FAA) imposes a minimum altitude limit of 1,000 feet above populated areas.

Many land management agencies, including the BLM, maintain collections of historical aerial photography of the lands they manage. The National Agriculture Imagery Program (NAIP) is managed by the U.S. Department of Agriculture Farm Services Agency (FSA) and acquires imagery of agricultural lands in the United States. Other governmental agencies work with the FSA to produce statewide coverage of natural-color, 1-, 2-, and 10-m resolution imagery that has been corrected for terrain and image distortions and is geospatially correct (orthorectified) on a cyclical basis. Information on these archives is available through individual agency websites. The BLM's aerial photography archive is maintained at the NOC.

Traditional, large-format (9-inch × 9-inch) aerial photography is film-based and is available in black and white, natural color, or color infrared formats depending on

the project requirements. Each aerial camera has its own camera calibration report. This is a report generated with the results of a series of tests developed to reveal the geometric characteristics of the camera and lens. The photogrammetrist uses this information in subsequent calculations to remove distortions, which helps to ensure a high-quality product. However, the imaging and mapping industry has started to migrate to a fully digital process in recent years. Often, traditional film is not used, as the imagery is captured in a digital format.

Presently, several sensor systems are able to capture aerial images digitally. The frame digital sensor is similar to a film camera in that it captures single frames. A push broom sensor (an array of several thousand charge coupled device [CCD] sensors) continuously collects data and then divides the data into frames. Digital images can also be captured in panchromatic, multispectral, and infrared modes simultaneously. This is advantageous because the images may be captured concurrently and do not require additional flights. Digital sensors also offer capabilities that allow the photogrammetrist to enhance portions of the image through image processing techniques to compensate for adverse conditions such as shadows or high-contrast areas. This allows data collection in areas that might be obscured on film.

Project Implementation

Many elements need to be considered to ensure that proper project design is met. These elements include the size of the area, scale of the photography, terrain (mountains or rolling hills), vegetation cover (desert or forest), accessibility (rivers, cliffs, or ownership restrictions), sun angle (latitude, longitude, or time of year), and type of sensor. Perhaps the most important

consideration is determining the level of accuracy necessary for the final product. Accuracy, photographic scale, and project size are directly related. Typically, the higher the level of accuracy required, the larger the scale of photography necessary, which in turn affects the magnitude and complexity of the job.

Photo Layout and Flight Line Index Map

One of the most important goals of project design is to ensure that there will be complete stereoscopic coverage of the area of interest, at the proper scale. Photo layout is a depiction of the extent of each photo in relation to the desired area of coverage. The graphic representation of the photo layout is often referred to as a flight line index map. Depending on the final photo scale, the flight line index map for traditional aerial photography flights are designed on 1:100,000- or 1:24,000-scale topographic or digital orthophoto maps (Figure 3). When designing the flight line, care must be taken to ensure that there is complete overlap between photographs. If more than one line of photographs is needed, there must be adequate side lap between the photos.

Survey Control

Another vitally important part of this process is the ground control survey. The survey is the link between the ground and the aerial photography. Surveys give the geospatial products their identity with regard to projection, coordinates, and final accuracy. A high level of accuracy (geodetic quality) is of the utmost importance when gathering the survey (horizontal and vertical) data. Locations for ground survey control points are indicated in the flight line map. Correct spacing and location of ground control survey points determine the area that can be mapped. Before the aerial photography acquisition, ground control panels or

targets must be placed on the ground as indicated by the flight line index map (Figure 4). A center point for each panel will be indicated by a monument (often with a survey nail or rebar driven into the ground). To make this point meaningful on the final aerial photographs, large "legs" of white material will be nailed down in a cross centered on the nail or

Figure 3. Examples of flight line maps and photo layouts.

Figure 4. Example of a simple, flight line layout indicating ideal locations for survey control points.

rebar. Ideally, high accuracy horizontal and vertical coordinates for each paneled point will be surveyed before the aerial photography acquisition.

Image Acquisition

After the project requirements have been developed and the flight line and control layouts have been designed, a specification package goes out to bid. At this time standard contracting procedures and schedules come into play. After the contract is awarded, coordination must take place between the contractor, NOC DRS staff, and the field office to ensure the ground control targets are in place before imagery is acquired. After the imagery is acquired, a review copy is provided to the Contracting Officer's Technical Representative for inspection. Once it has been determined that the aerial photography meets the contract specifications, the imagery is accepted. The aerial film and paper prints (if requested) or digital files are then provided to the NOC for processing and inclusion in the BLM's aerial photography collection.

Interpreting the Imagery

The process of extracting data from the aerial imagery begins with combining the digital imagery with the ground control coordinate data. These imagery files can be supplied directly from a digital sensor or by scanning aerial film. Film scanning is performed with an extremely accurate

(micrometer accuracy level) scanner. The result is a digital representation of the film. The photogrammetric workstation re-creates the geometry of the field subject through a series of mathematical calculations. Aerotriangulation is a mathematical process (least squares bundle adjustment) by which the survey data are used to tie the photos together and adjusted coordinate values are distributed throughout the entire project. The oriented image files are displayed on a computer monitor in a way that enables the operator, equipped with a pair of specially designed glasses, to view the digital image files in a 3D environment. In this virtual environment the photogrammetrist can record (or compile) the horizontal and vertical data necessary for producing a reliable map directly into a geospatial data file.

Photogrammetrically Derived Products

A large variety of 3D digital data in support of land use planning and decision making can be developed from both aerial and close-range photography. The photogrammetric process enables the interpretation of imagery and the collection of data necessary to produce reliable maps that support land managers' decisions and are defensible in court. These data customarily take the form of topography (terrain or land surface) or planimetric (such as streams, transportation routes, vegetation boundaries, and cultural) information.

Digital Terrain Model

A digital terrain model (DTM) provides a digital representation of the terrain surface. A DTM can be produced in a manual or automated mode. Manual mode is a process in which a specialist, using a photogrammetric workstation, observes each point in accordance with a specified spacing and records its location, both horizontally and

vertically. Automated digital terrain extraction is commonly referred to as autocorrelation or digital image matching. It is a process in which sophisticated software matches pixels (picture elements) with unique spectral and geospatial values in one digital image to similarly valued pixels in the adjacent image of the stereo pair. The addition of more information, such as breaklines (polylines in which each vertex has its own x, y, z, location) may be required to aid the software in determining pixel matches in difficult-to-interpret areas. Topographic contour lines can be generated by using DTM, breakline, and planimetric data.

Digital Orthophoto

A digital orthophoto is a photograph that has been corrected to eliminate distortions and differences in scale (Figure 5a.). The effects of camera tilt and relief displacement (features at higher elevations are displaced away from the center of the photo) are the main causes of these distortions. To eliminate these, the ground geometry is re-created as it would appear from directly above each point in the photo. This is accomplished by applying a process called differential rectification to each pixel in the image. The resulting corrected image can be used as a map.

The orthophoto can be printed as a stand-alone product or displayed as a backdrop with other spatial information. Perspective views can be produced by draping the orthophoto image over the terrain surface. This process allows one to make a “virtual” visit to the area. The parameters of this virtual surface can be further manipulated to enhance, exaggerate, or isolate a certain feature or part of the image. Topographic contours and planimetric data can be draped onto the orthophoto in three-dimensional space. This virtual visit can be extremely useful for land use planning decisions and communicating with the public.

Vector Map

Vector data customarily take the form of topography (terrain or land surface) or planimetric (streams, transportation routes, vegetation, and cultural) information. Planimetric features are compiled in a manual mode, in which the photogrammetric operator digitizes (in real-world coordinates) points, lines, or polygons representing features of interest (Figure 5b and 5c). The resulting data files can be imported directly into ArcMap for GIS use or into AutoCAD for engineering design.

Figure 5. a. Digital orthophoto map. b. Vector map depicting roads and topography. c. A combination of the vector map overlain on the digital orthophoto map. These digital products were created photogrammetrically at the BLM National Operations Center (Denver, Colorado) in support of remediation at the Rip Van Winkle Mine site in Elko County, Nevada.

Imagery captured from a variety of perspectives such as this image of a mesa west of Kanab, Utah, can be acquired from aerial platforms.

CLOSE-RANGE PHOTOGRAMMETRY

The same basic principles of traditional aerial photogrammetry can be applied to stereoscopic pictures taken from lower altitudes or from the ground. Terrestrial, ground-based, and close-range are all descriptive terms that refer to photos taken with an object-to-camera distance of less than 300 m (1,000 feet). This distance equates to the minimum safe flying height above populated areas, as required by the FAA. Since the same basic principles apply to photographs taken from a camera mounted on a tripod (terrestrial) or suspended from a light sport aircraft (low-level aerial), both types of nontraditional photogrammetry are referred to in this report as close-range photogrammetry (CRP).

A variety of cameras and platforms may be used to obtain the photographic images to be used in CRP processing, including cameras housed in unoccupied airborne vehicles, suspended below helium-filled blimps, and mounted on tripods (Figure 6; Breithaupt et al. 2004). Through the use of these nontraditional methods, a resolution or ground sample distance of 0.25 mm and

a spatial accuracy equivalent to 0.025 mm can be achieved. Theoretically, there is no limit to the resolution that can be achieved from CRP images (Matthews et al. 2006).

The BLM's national center in Denver has used close-range photogrammetric techniques to document resources since the late 1980s. At that time, although producing high-quality results, the close-range photogrammetric process could be tedious and time-consuming mainly because of the need to apply traditional techniques, workflow, and equipment to close-range image capture and processing. However, recent advances in commercially available and cost-effective three-dimensional measuring and modeling (3DMM) software, high-resolution digital cameras, and high-performance laptop computers have revolutionized the CRP process. With these advances, the photogrammetric process can be moved from the laboratory environment into the field, and taken strictly from the hands of the photogrammetry expert and moved to the hands of the resource specialist.

Figure 6. A variety of cameras and platforms may be used to obtain the photographic images used in close-range photogrammetric processing, including cameras housed in unoccupied airborne vehicles, suspended below helium-filled blimps, and mounted on tripods. All images were taken at the BLM's Red Gulch Dinosaur Tracksite in Wyoming.

Close-Range Photogrammetry Workflow

As with traditional photogrammetry, the first step in the close-range project workflow is establishing project requirements. These requirements include the area to be covered, type of ground cover, access to areas surrounding the subject, weather, accuracy of the final product, format of the final product, public visitation at the site, and others. However, with the relatively recent availability of reasonably priced, high-quality digital cameras and 3DMM software, many of the traditional requirements in the photogrammetric process can be accomplished in nontraditional ways, providing a high level of flexibility.

An example of the increased flexibility can be seen in image acquisition. In most situations, a person who is experienced with CRP (such as the staff at the NOC), using a high-resolution commercial digital single-lens reflex (SLR) camera, can successfully capture ground-based photographs for a variety of projects. Most persons, following a few simple rules and taking good-quality photographs, can capture the images necessary for completing a successful CRP project. See Appendix C for more details on taking proper photographs and camera requirements and settings.

Project Design

Once project requirements have been determined, the process of project planning can begin. Accuracy, photographic scale, and project size are directly related. Typically, the higher the level of accuracy required, the larger the scale of photography necessary, which in turn increases the magnitude of the job. CRP projects can be placed into one of two categories. These categories are small (simple) and large (complex).

Small projects are those for which the area of interest is equivalent to about 5 m² or smaller. This type of project may also be referred to as extreme close range, as a high precision of data points is expected. Although proper planning strengthens any project, the small terrestrial project may afford greater flexibility in the planning process. Project design and image acquisition for projects of this scope may be successfully carried out by the resource specialists in the field. By following a set of standard operating procedures (Appendix C), successful completion of the capture of imagery for an extreme close-range project may be accomplished.

Large projects are those for which the area of interest is greater than 5 m² or where complexities of terrain or access add to the level of expertise needed for planning and execution of the project. Projects that fall into this category may require a preliminary site visit or the inspection of overview photographs taken of the area. A preliminary reconnaissance of the area will determine if close-range photogrammetry is the best method for data capture, and if so, estimate resources necessary to accomplish the project. Also at this time, the data requirements and expectations of the end user can be discussed. Projects of this scope are best accomplished by those who have experience with close-range image capture and processing.

Sometimes the needed vantage points to capture imagery may not be present, necessitating alternatives to ground-based capture. In these situations, a large ladder, aerial blimp, UAS, or other type of elevated platform may be needed. For these reasons, it is advantageous to contact the photogrammetric specialist for consultation early in project development to help with such items as budget, scheduling, site visit input, and others.

Photo Layout

Close-range photogrammetric projects have more latitude in their design and execution than do traditional aerial projects because the 3DMM software is more capable of handling photographs taken at oblique angles to the subject and in connecting lines of stereophotos that have less consistent overlap than conventional aerial photogrammetry software. Nonetheless, knowing the lay of the land in advance can be critical to project success. This type of evaluation can be gained either through an onsite visit (which is preferable for complex projects) or from inspection of existing imagery. This imagery may take the form of snapshots of the area taken from the ground or existing, small-scale aerial imagery. It is a good investment in time and resources to investigate the existence of digital orthoimagery, which may be available over the Internet, or historical, large-format aerial photography available from agency collections. Site reconnaissance not only aids in identifying strategies for capturing complete stereoscopic coverage of the subject, but can also be used to identify obstacles to imagery acquisition. These obstacles most often take the form of vegetation, which can obscure points of view and terrain issues. Terrain obstacles can range from a lack of an elevated perspective to perilous drop-offs adjacent to the subject of interest.

While the formal flight line index map described previously in the aerial photogrammetry section may be bypassed for simple close-range projects, preplanning can certainly maximize field time, as it would calculate the object-to-camera distances, proper base-to-height ratio, and size and number of reference targets. However, flight line planning is advised for complex projects, especially those using photographs taken from a light sport aircraft or UAS. In these instances, a formal

flight line index map may be required to convey expectations to the pilot.

Survey Control

“Surveyed” ground control is not needed for a CRP. During the 3DMM processing, the camera lens system is calibrated. This technique elevates the camera from simply a device for capturing images to a virtual surveying and data collection instrument. By placing an object of known length in the overlap area of stereo models, a very accurate coordinate system can be created. However, GPS survey does give the products an identity as far as projection, coordinates, and final accuracy are concerned and can be easily integrated into a CRP project.

Image Acquisition

The increased flexibility provided by CRP is most completely realized in the image acquisition. Because many of the rigors imposed by traditional photogrammetric processing are removed from CRP, almost any person who can take good quality photographs can take the photos necessary for 3D data processing (see Appendix A). This can be most successfully realized when field personnel have undergone training or thoroughly read this technical note and have completed their own small project. For a large CRP project, a person who is experienced with CRP, such as the staff at the NOC, can successfully capture ground-based photographs for a variety of projects.

When the needed vantage points to capture stereoscopic imagery cannot be attained from a ground-based setup, it will be necessary to investigate more “airborne” options. This may include simply using a ladder or elevated platform to obtain the needed perspective. However, when the area to be documented is large and there is no opportunity for oblique image collection, it may be necessary to employ the use of some type of low-level

aerial system. In such instances, it will probably be necessary to go through a commercial provider as is done with traditional aerial imagery acquisition.

Interpreting the Imagery

The process of extracting data from the CRP imagery is another area where increased flexibility is realized compared to traditional aerial photogrammetry. The 3DMM software can run very efficiently on most laptop computers. Thus, processing

of digital images may begin in the field as soon as the imagery is acquired and downloaded. This can provide a real time look at the success of the photography coverage and provide for near real time measuring and recording of features. In addition, the photographs may be taken by trained field personnel and archived for later processing in a workstation environment. The resulting 3D image files can be, in turn, sent back out to field personnel for viewing in free viewer software. If more in-depth analysis is required, ArcGIS Stereo Analyst and LIECA Photogrammetric Suite (LPS) (both available within the Bureau) can be used for data compilation.

Figure 7. a. Digital orthophoto map. b. Vector map depicting topography. c. Digital terrain surface colorized by elevation. These maps were produced by photogrammetry at the BLM National Operations Center (Denver, Colorado) with a tripod-based camera and close-range photogrammetric techniques; they depict a dinosaur trackway from the BLM's Red Gulch Dinosaur Tracksite in Wyoming.

Close-Range Photogrammetry Products

The same cadre of products (digital terrain model, digital orthoimagery, vector maps, and others) that can be created from traditional aerial photogrammetry can also be generated from CRP (Figure 7). In addition, new and unique visuals can be easily produced from within the 3DMM software (Figure 8). Therefore, it is much

more efficient to produce animations and digital-rotatable 3D objects that can be integrated into 3D raster streaming Web technology. A 3D Adobe Portable Document Format (PDF) file can be produced and embedded in PowerPoint presentations and documents. In addition, the dense and accurate 3D surface files can be used to produce solid model printouts using a variety of techniques at very large scales, even 1:1.

Figure 8. Three-dimensional surface and image datasets can be packaged as industry standard files that can be viewed and rotated in 3D by a number of software programs. Shown is a right angle cliff face from the Bighorn Basin, Wyoming.

Getting a better vantage point to photograph a test plot in the Falcon Road Open OHV area within the Gunnison Gorge National Conservation Area near Montrose, Colorado.

EXAMPLES

Cyclic Documentation for Change Detection

The ability to detect small changes in soil movement can provide valuable insight for assessing the effects of surface disturbing activities across the landscape (Matthews et al. 2007). Close-range photogrammetry is an excellent method for capturing detailed information about changes, such as erosion, on scales ranging from 1 square meter plots up to an entire hillslope. CRP is especially effective for monitoring erosion on areas that are devoid of vegetation, such as roads, OHV trails, and construction sites (Ypsilantis, personal communication).

Close-range photogrammetry was used to create 3D surface information to help quantify effects from rapidly increasing off-highway vehicle (OHV) use in the BLM's Uncompahgre Field Office. In August 2005, five permanent, variable-sized plots were established north of Montrose, Colorado. Two sites are located in dry wash channels, which cut through sandstone, shale, and coal, in the Dry Creek Extreme OHV Area. An additional three sites were located in the Falcon Road open OHV area within the Gunnison Gorge National Conservation Area (Figure 9) on adobe badlands composed of Mancos shale (Ypsilantis et al. 2007).

Natural features, such as bedrock (when present outside the traveled area) or rebar plot control stakes, served as *x*, *y*, *z* coordinate reference points. The rebar plot stakes were buried beneath the soil surface to ensure that the permanent reference points were not disturbed and to eliminate safety hazards for recreational users. A series of stereoscopic photographs were taken of the plots, concurrently with the camera calibration photographs, to facilitate stereoscopic viewing and analysis of the subject area. Establishing plots, site

Figure 9. Five permanent study plots were established in 2005 in the vicinity of Montrose, Colorado: A. Scratch and Dent; B. Calamity; C. Falcon; D. Falcon II; and E. Beyond Falcon (Ypsilantis et al. 2007).

preparation, and photographing for all five plots were accomplished in 2 days.

In September 2006, the five plots were reestablished and site preparation, GPS coordinate collection, and photography were conducted in 1 day. Real-time kinematics (RTK) GPS positions (accurate to <1 cm) were taken for the control monuments and selected points within each plot locality. The resulting coordinate data were used to tie the digital terrain models to a real-world coordinate system (NAD83 Colorado Central State Plane Zone). In addition, this control was used to process both the 2005 and 2006 photography to aid in ensuring positional integrity between the 2 years (Ypsilantis et al. 2007).

Ten unique, highly detailed 3D surface datasets were produced photogrammetrically. The estimated vertical accuracy

of these data is between 0.1 and 1.0 cm. The ten (2 years for each of five plots) 3D digital terrain datasets were analyzed in ArcGIS by using ArcMap and ArcScene. This process included creating a tin surface from the 3D datasets, converting the tin to a grid, and generating a hillshade from the grid (Figure 10). The grids were created with a resolution of 3 cm. Cut-and-fill and surface subtractions were made using the surface grids (Figures 10 and 11). According to the results of the analysis of the surfaces, all five sample plots exhibit loss and gain (or movement) of soil.

The soil gains and losses on the Mancos Shale hillslopes in the Gunnison Gorge NCA are high, with average soil loss rate of 163, 219, and 121 tons/acre calculated for the three sites. Figure 11b illustrates an area of high impact at the top of the slope at one site and an area of minimum impact at a similar slope position. The soil loss for the area of high impact was 585 tons/acre and 367 tons/acre for the area of minimum impact. This indicates that soil loss is greater in the dirt bike trail entrenched into the hillslope than in the area that showed little visual evidence of recent OHV use (Ypsilantis et al. 2007).

Figure 10. Falcon II plot. a. Photograph taken in August 2005. b. 3D surface model generated from the 2005 photography rendered as a hillshade. c. Photograph taken in September 2006. d. 3D surface model generated from the 2006 photography rendered as a hillshade (Ypsilantis et al. 2007).

Figure 11. Falcon II plot. The 3D surfaces generated from the 2005 and 2006 photography were compared in ArcGIS. a. Graphic generated by using surface subtraction of the 2005 surface from the 2006 surface. The dark blue and dark red colors represent areas of greatest separation between the two surfaces. b. Falcon II plot. Volumetric loss between 2005 and 2006 for two areas of 17.77 m³ (Ypsilantis et al. 2007).

The Dry Creek Basin sites were along a trail in an ephemeral drainage area. The modified OHVs on the trail can climb boulders and dig the sides of their tires into the hillslopes (Figure 12). This results in deposition of soil material below that hillslope, which is available for transport by the stream during high precipitation. One interesting anomaly shown in Figure 13 is the two large boulders that have been moved approximately 2 m downslope, apparently by OHV activity. The amount and direction of movement could be reliably determined through the use of stereoscopic images taken during the study.

The results of the study were compiled into a report (Ypsilantis et al. 2007) and provided to the Uncompahgre Field Office for use in the travel management plan. In addition, graphics generated from the report are being used in public presentations in support of management decisions.

Figure 13. Scratch and Dent plot. Two boulders (A and B), each approx $1 \times 0.6 \times 0.5$ m, moved about 2 m down the channel (A' and B') between August 2005 and September 2006 (Ypsilantis et al. 2007).

Integrating Multiscale Imagery for Riparian Habitat

Coalbed methane discharge water has the potential to influence aquatic and riparian habitats in and along the Powder River of northeastern Wyoming (Figure 14). The Powder River Aquatic Task Group is investigating the use of remote sensing data and techniques to develop economical and effective means of monitoring change in affected aquatic and riparian habitat (Figure 15). This study is evaluating the utility of very large scale aerial (VLSA) imagery for classifying riparian and aquatic habitat types, as well as testing close-range photogrammetric, stereo-based image modeling techniques for change detection, documentation of vegetation composition and structure, and quantifying bank erosion and stability (Bobo et al., 2008).

A transect-based aerial-sampling protocol was proposed for the first phase of this project to facilitate the capture of ground control to support the CRP work. In related work, the integration of GPS/IMU systems with CRP techniques to accurately and rapidly geocorrect VLSA photography is being explored. The georeferenced VLSA imagery can in turn be used as training data for wider area mapping by using

Figure 14. Location map for the Powder River, Wyoming, coalbed methane aquatic monitoring study (Bobo et al. 2008).

satellite platforms such as Quickbird. Georeferencing of the VLSA imagery is presently conducted with both 0.60-m resolution Quickbird imagery and 0.25-m resolution AeroCam imagery (Noble et al. 2008; Figure 16). Once the spatial links between the three sets of imagery were set, the VLSA was used as a classification tool for the more coarse resolution imagery.

Figure 15. 3D image model developed from close-range photogrammetry along the Powder River, Wyoming. Images from two different times of year are merged to highlight the change in vegetation. With the 3D information available from multi-temporal 3D dataset, changes in vegetation heights, bank erosion, slope, water depth, vegetative cover, and bare ground can be measured (Noble et al. 2008).

Figure 16. Photo targets were placed along selected transects across the Powder River, Wyoming, to assist with geocorrection of large-scale aerial imagery (Noble et al. 2008).

The integration of GPS/IMU systems, VLSA imagery, and CRP techniques hold the potential to greatly expand field sampling intensities, thus enabling more representative coverage of the environmental gradients in the landscape. This will lead to better monitoring information and increased classification accuracies of coarse-scale remote sensing data. Additionally, the integration of these technologies would facilitate the development of proactive monitoring protocols for invasive species.

At all three study sites for which VLSA imagery was obtained, tamarisk (*Tamarix spp.*)—a salt-accumulating, desiccation-tolerant invasive alien species—was shown to have cover values comparable to the

native cottonwood (*Populus fremontii*). Given the high percentage of emergent features of the Powder River channel and the documented tamarisk succession scenarios of other western streams, tamarisk poses an immediate threat to the aquatic habitat and native riparian vegetation. By automatically geocorrecting VLSA imagery using the integration of GPS/IMU systems, great potential for cost-effective monitoring exists. This will allow for the development of protocols for riparian corridors that would enable invasive species to be identified before becoming so infested in an area that management actions become too expensive to implement (Bobo et al. 2008).

Documenting Cultural Resources

The Legend Rock State Archaeological Site enables visitors to view more than 300 petroglyphs spanning a period of thousands of years and representing multiple cultures. Legend Rock, located 28 miles from the town of Thermopolis in north-central Wyoming (Figure 17), was listed on the National Register of Historic Places in 1973 and is world-renowned. A series of sandstone cliffs contain the petroglyphs. Ownership of the cliffs is split among a private land owner, Wyoming State Parks, and the BLM. In 2006, the Legend Rock Interagency Steering Committee was formed. This Committee includes land management agencies, as well as State and local preservation groups and museums. The mission of the Committee is to provide guidance and recommendations to the Wyoming Division of State Parks and Historic Sites on the restoration, maintenance, management, interpretation, promotion, and public accommodation at the Legend Rock State Archaeological Site (Loendorf et al. 2008).

Figure 17. The Legend Rock State Archaeological Site is 28 miles from Thermopolis in north-central Wyoming.

Photogrammetry staff from the NOC was included in the committee from its inception. In fall 2006, NOC staff, accompanied by imaging specialists for Cultural Heritage Imaging, a nonprofit organization that is developing an imaging technique (Mudge et al. 2006) complementary to CRP, joined archaeologists for a visit to the site. This reconnaissance visit provided an opportunity to see and access the site and to determine the approach and resources needed to fully photograph the rock art panels. As a result of the scoping trip, several proof-of-concept 3D image datasets were produced. These virtual 3D models and the CRP techniques were presented at committee meetings, professional archaeological meetings, and for the 2007 Wyoming Joint Senate House Subcommittee on Recreation, Travel, Wildlife, and Cultural Resources. The 3D models provided stunning visualizations of the intricacies and uniqueness of the rock art, offering an early success and a catalyst to energize the committee (Figure 18).

A multiphased approach for documenting the site was developed. During the first phase, a spatially accurate photographic mosaic base map of the sandstone cliff was created. The corrected mosaic, tied to a digital real-world system with RTK GPS, served as base maps for field location,

Figure 18. The close-range photogrammetric digital 3D image models can be created and viewed on a laptop computer in the field, providing an on-site demonstration.

inventory, and documentation of rock art panels. The cliff face was photographed from a distance of about 200 m with a 150-mm lens (Figure 19). A resulting resolution and positional accuracy of about 1 cm was achieved (Figure 20). In addition, the digital photo mosaic can be used to provide visual context to more detailed, three-dimensional digital models of individual panels.

The second phase provides detailed three-dimensional modeling and imaging of individual petroglyph panels. The virtual models can be used to record the petroglyphs and to detect even minute changes to the rock art that may occur over time. These highly detailed digital re-creations of the individual panels provide a resolution and accuracy in the tenths of millimeters and provide a baseline for monitoring the site for natural degradation and vandalism. Because of the enormity of the workload for DRS staff, the NOC photogrammetrists provided training in stereoscopic image capture to a State of Wyoming archaeologist involved in the project (Figure 21). In summer 2007, all the

panels on the State-managed land were successfully photographed. In summer 2008, the remaining rock art panels were photographed during a Passport in Time (PIT) project. The PIT program, originated by the Forest Service, allows qualified volunteers to assist in the restoration, recording, and preservation of cultural resource sites. During the 2-week program, photogrammetrists from the NOC provided training in stereoscopic image collection and software processing to the PIT volunteers (Loendorf et al. 2008).

Since the formation of the Legend Rock Interagency Steering Committee, funding for the site has increased, resulting in improvements to infrastructure. An archaeological survey was conducted (Walker et al. 2007) before improvements were made to roads, trails, and parking. The construction of a visitor's center and accommodations for a site host are under way. The photogrammetric documentation will be used as a baseline for inspection and monitoring and for interpretive materials, to include a guide book for the site and interactive digital displays that

incorporate the virtual 3D image models. In addition, the Wyoming Joint Senate House Subcommittee on Recreation, Travel, Wildlife, and Cultural Resources

made the preservation and interpretation of Wyoming's cultural resources its first priority for interim study in 2008.

CONCLUSION

Documenting and evaluating the condition of its land is a critical part of the Bureau's mission. Condition data obtained by applying photogrammetric techniques provide information on the health of the land and serve as a basis for future decision making; they also provide a tool for determining the effectiveness of present management practices. The availability of digital cameras and the increasing capabilities of computers and analytical software have dramatically expanded the variety of resource applications to which photogrammetry may be applied, while simultaneously decreasing the costs of acquisition, processing, and analysis. The software used to process stereoscopic images to the viewing stage (corrected imagery and 3D surface data) and for use in GIS is presently available within only a few BLM offices. However, the capability to take the needed photographs for close-range photogrammetric projects is not. Field personnel with a vision toward the future will see the value in capturing stereoscopic photographs now. As the types, capability, efficiencies, and availability of 3DMM software increase, these photographs can be used in the future to document changes in condition critical to the Bureau's mission.

The fundamentals of perceiving depth, stereoscopic viewing, and photogrammetry have remained constant through changing technologies. Various 3DMM softwares available on the market today may suggest additional photographs

to increase efficiencies. However, the basic geometry will remain the same and allow for measurements to be made from stereoscopic photographs taken 100 years ago, yesterday, or 100 years in the future. Because of this, the concepts of capturing the data and not processing via specific software have been stressed in this document.

The following appendices contain technical information to assist field resource specialists in the successful completion of the imagery collection portion of a basic close-range photogrammetry project. Appendix A outlines the basics of stereoscopic photography. Appendix B discusses the features that should be considered when choosing a camera for CRP documentation. Appendix C discusses factors that can affect picture quality and offers suggestions on taking photographs that will provide successful results. Finally, Appendix D outlines the general steps for conducting the field collection of the photographs for a small CPR project. Also included in Appendix D is an equipment list. When reviewing this list, note that the majority of items (with, perhaps, a few exceptions) are the standard equipment most often taken to the field. That is the benefit of CRP: for the initial field trial of this technology, there is no substantial investment in equipment, only of time—time to read and be familiar with the contents of this document and time to practice taking the needed photographs in the field.

A fixed grid of varying height was used as an early method of providing x,y, and z control at the Red Gulch Dinosaur Tracksite in Wyoming.

● APPENDIX A

CONCEPTS OF STEREOSCOPIC PHOTOGRAPHY

Stereoscopic photographs are taken to mimic the three-dimensional viewing capability resulting from the offset of a person's left and right eyes (Figure A.1). The first consideration when designing the stereophoto layout is the needed precision

(scale) that is required to adequately represent the subject. As in traditional film photogrammetry, the scale has a geometric relationship between the height of the sensor and the focal length of the lens (Hussain and Bethel 2004).

Figure A.1. Stereoscopic photograph pairs of a dinosaur track from the Red Gulch Dinosaur Tracksite, Wyoming.

Figure A.2. The large black dots represent photo centers and thus the camera position. A dashed rectangle is associated with each photo center dot and represents the field of view, or footprint, of that image. The best stereophoto pairs overlap each other by 60%. This is achieved by actually moving the camera position of each photo by 40% of the photo's footprint.

Figure A.3. In this example, each image footprint is 1.65 m, thus the amount of stereoscopic overlap (at 60%) is 0.99 m ($0.60 \times 1.65 = 0.99$). To achieve 60% overlap, the camera must be moved by 40% of the image footprint, which is 0.66 m ($1.65 \times 0.4 = 0.66$).

Figure A.4. Graphic of parallel images with typically 60% overlap (Birch 2006). An imaginary ray (dashed line) drawn through the center of the lens should be as perpendicular to the plane of the subject as possible. All images are taken with one camera that is moved in sequence from position one to two, to three, and so forth.

$$\text{scale} = \frac{\text{focal length}}{\text{height above terrain}}$$

For example: $\frac{6 \text{ inches (0.5 feet)}}{2,000 \text{ feet}} = 0.00025$

$$1/0.00025 = 4,000$$

$$\text{Scale} = 1:4,000$$

The pixel resolution, or Sensor Pixel Size (SPS), of a commercial digital camera can be factored into the preceding equation to determine the ground resolution, or ground sample distance (GSD), of the resulting image. The SPS is computed by taking the physical width of the sensor divided by the width of the sensor in pixels.

$$\text{GSD} = \text{SPS} * H / f$$

where SPS is the Sensor Pixel Size (in micrometers),

H is the camera height, or distance from the object (in meters), and f is the focal length of the lens (in millimeters).

GSD will be in meters; multiply by 1,000 for GSD in millimeters

The best stereophoto pairs have an overlap of 60% (Figure A.2). Once the desired GSD is determined, the camera height and distance between camera stations can be calculated.

For example, when using a 10 megapixel SLR with a sensor size of 23.6 × 15.8 mm and pixel dimensions of 3,872 × 2,592, the $\text{SPS} = 23.6 / 3,872 = 0.00610 \text{ mm}$. Therefore, with a 20-mm lens, and shooting at a height of 1.4 m above the subject, the GSD—is 0.43 mm. The area covered (or footprint) of each photo would be 1.65 × 1.11 m. For a 60% overlap, the distance between camera stations is 0.66 m, which is 40% of the image footprint (Figure A.3).

A simple way to determine the image footprint in the field is to mark points on the ground on either side of the frame of the viewfinder when the camera is at the appropriate distance from the subject. Then measure the distance between these points and calculate 40% of that distance.

The orientation of the camera or sensor to the subject is also an important consideration. It is most desirable to have imagery that is taken as close to nadir—that is, with the camera perpendicular to the subject—as possible. A tripod (with an extension arm when shooting down) can greatly aid in positioning the lens directly over the subject (Figure A.4). This also positions the plane of the sensor parallel to the subject and helps to reduce perspective distortions in the image (Figure A.5).

In some instances, nadir photography is not practical because of constraints imposed by the terrain or project size. In such instances, oblique photography must be used.

Photographs deviating significantly from nadir that have a high angle to the object are referred to as high-angle oblique photos (Figure A.6a). When nadir photos are not a practical option, high-angle oblique

Figure A.5. It is important for the camera to maintain a consistent relation to the subject. Keeping a perpendicular angle to the subject is preferable. The dashed line represents the ray described in Appendix Figure A.4. A tripod with an extension arm was used when photographing a dinosaur trackway at the Red Gulch Dinosaur Tracksite, Wyoming.

photos are preferred for several reasons: ability to get closer to the subject while still filling the frame, stronger angles for resolving the 3D coordinate positions, and less distortion of features.

Photographs taken at a low angle to the subject are referred to as low-angle oblique photos (Figure A.6b). Low-angle oblique photos are not desirable, as both the subject and control targets can be highly distorted. However, if an in situ object is being photographed and low-angle oblique photos are the only option, they may be used. With experience and care, low-angle oblique photos may successfully be used for measurement.

Figure A.6. A line of sight not directly nadir (perpendicular) to the subject is considered oblique. a. Photos taken at a high-angle oblique camera angle can be used when needed and will provide successful results. b. Photos taken when the line of sight to the subject is sharp (a low-angle oblique camera angle), should be avoided unless absolutely necessary to provide stereo overlap.

Extending the reach to photograph a difficult to access rock art panel in the Bighorn Basin of Wyoming.

● APPENDIX B

CHOOSING A CAMERA

Digital cameras and 3DMM software have most certainly revolutionized the CRP process. Previously, an expensive metric or surveying camera was required. These cameras are equipped with required fixed-focus lenses with predetermined focal distances and are manufactured to a high level of precision and stability. However, even with care in manufacturing, lens distortions could not be completely eliminated and a manufacturer's calibration report would accompany each camera. The calibration report includes the size of the frame, location of any fiducials, the focal length, principal point, and distortion coefficients of the camera–lens system. The information from the calibration report is used in setting up the stereo model so that the resulting measurements could be made without the effects of distortion from the camera–lens system.

Now the 3DMM software allows us to exploit the ever-increasing number of digital cameras on the market today. The main reason for this is that the 3DMM provides a camera calibration function. This not only removes the restriction of using an expensive metric camera, but also allows for the ad hoc calibration of most camera–lens systems. This is exciting, as it provides for the capability to increase the ground sample distance (GSD) as cameras come on the market with improved sensors. However, it also makes it difficult to suggest a particular camera, as innovations seem to occur frequently. It is important to note that, whereas a digital SLR camera is suggested, successful projects can be accomplished with a point-and-shoot camera. Thus, the following recommendations

highlight features to consider when choosing a camera for CRP documentation.

Resolution

The final accuracy of your measurements and resulting terrain surface are governed by the resolution, or GSD, of the stereoscopic images of your subject. The GSD is governed by the resolution of the camera sensor (higher is better), the focal length of the lens, and the distance from the subject (closer is better). The resolution of the images is governed by the number of pixels per given area and the size of the sensor. A 6 megapixel resolution generally provides good results for a variety of subjects. However, an 8 to 10 megapixel resolution provides much more flexibility and achieves higher accuracies. The sensor size does have to be considered along with the resolution. The conventional way to categorize digital camera sensor size is similar to the sizing of television screens; that is, dimensions are given across the diagonal. The ratio of the sensor is often compared to the 35-mm film that it has replaced (43.3 mm diagonal). The sensor does have a bearing on image quality, with the 28.4 mm sensor found in most digital SLR cameras having the best quality. The sensors of midrange cameras are often 11.0 mm, whereas those of compact digital cameras are 6.72 mm. These smaller sensors can introduce noise in the image. Thus, a compact digital camera with a 1/2.7-inch sensor, even at 12 megapixels, would produce a less desirable image than one with a 11.0 mm sensor, at 8 megapixels.

Lens Flexibility

The length of the lens directly affects the field of view (the base-to-height ratio, the distance from an object and, finally, the accuracy and number of photos needed to cover a subject). Shorter lenses (18 to 30 mm) provide the widest field of view and are good for capturing a subject from close distances with a minimal number of photographs. Longer lenses (100 to 300 mm) are excellent for capturing a subject from greater distances but provide a narrower field of view. However, it can be expensive to have a variety of fixed-length lenses on hand.

Many digital SLR cameras are sold in a “kit” with a compound zoom lens. A fixed-focus lens will always produce a higher quality image; however, the kit lenses are good in that they provide versatility and can reduce start-up costs. Successful CRP projects can be accomplished with zoom lenses when special care is taken.

Manual Focus

Ensuring that a series of stereophotos are captured at the same focal distance is vital to the successful completion of a project. The capability to “take control” of the focus from the camera is accomplished by the manual focus setting. Most SLR and midrange consumer cameras have this capability. The manual focus setting helps to ensure that each photo in the stereo sequence is taken with the same focal distance (although autofocus can be used as long as a constant distance between the camera and the subject is maintained).

Aperture Priority

The aperture setting not only determines the amount of light that reaches the sensor but also controls the depth of field (the point at which the image begins to blur). Thus, it is necessary to use a camera for which the aperture can take priority over the other settings that affect the lighting, such as shutter speed or ISO (International Organization for Standardization; http://www.dpreview.com/learn/?/Glossary/Digital_Imaging). Although this feature is standard on digital SLR cameras, it may not be available on compact cameras.

Image Format

There are a number of different digital image formats. Each format has advantages and disadvantages based on the use and type of compression. Digital image files that are unprocessed, or RAW, contain the original information from the sensor and capture a greater bit depth than other standard formats. The RAW images must be processed in some type of image manipulation software, which often comes with the camera, or third party software such as Adobe Photoshop. The ability to manipulate the RAW image provides for the opportunity to make some exposure corrections after the photos are taken and may allow for the extraction of detail in areas of deep shadow. Other types of image files, such as .jpg (Joint Photographic Experts Group) and .tif (Tagged Image File Format), are processed within the camera and will not provide the same amount of flexibility in post processing (http://www.dpreview.com/learn/?/Glossary/Digital_Imaging). Cameras that capture images in RAW file format, or a combination of .jpg and RAW, are preferred.

Lens Distortion

All camera lens systems have distortions because of the curvature of the lens and the alignment of the lens with the sensor. To quantify these distortions and effectively remove them, 3DMM software provides camera calibration functions as part of the project workflow (Figure B.1). The additional images needed for the camera calibration can be easily integrated into the stereoscopic workflow and are discussed in Appendix C.

The following cameras have been successfully used within the BLM for CRP projects: Canon Powershot A640; Olympus C8080 and EV500; Nikon D70, D80, D200, and D3; and Canon 5D and 1D.

Figure B.1. a. Photograph of a straight-line rectangular grid. The curvature of the lines is due to the most common type of lens distortion, which is barrel distortion.

a.

b. Graphic representation of lens distortion. The least distorted portion of the lens is in the center (depicted in blue). During the camera calibration process, the focal length, format size, principal point, and distortion coefficients (K_1 , K_2 , K_3 , P_1 , and P_2) of the camera-lens system are calculated.

b.

c. The corrected photograph from a. after the lens distortion parameters were applied. The results can be seen in the straightening of the grid lines and a visible change of the image.

c.

Due to the minimal equipment requirements of close-range photogrammetry, subjects in difficult terrain, such as this area north of Albuquerque, New Mexico, can be documented more readily.

● APPENDIX C

TAKING GOOD PICTURES AND SUGGESTED CAMERA SETTINGS

The crucial element to a successful close-range photogrammetric process is attaining “good” photographs. In this instance, the term good refers to a series of pictures that have uniform exposure and are high-contrast, sharp images that fill the frame with the subject. Close-range photographs may never appear on the cover of *National Geographic* magazine or thrill your friends and neighbors, but they must be of sufficient quality that the autocorrelation function of the 3DMM software can function properly.

Environmental factors, the camera used, and the experience of the photographer all contribute to the success of the CRP project. The following section offers recommendations for composing your photos and correctly adjusting the camera settings. It is important to have adequate experience with the camera you are using and be able to adjust it to meet the circumstances. If you can operate your camera and understand the techniques for capturing CRP, you will be able to document, in measurable 3D, almost any subject at almost any time, just with a camera and your brain.

Taking Good Pictures

Several requirements must be met when taking photos suitable for photogrammetry. Every photo needs to be clear, properly exposed, and have adequate overlap with adjacent photos (Appendix A).

Lighting is one of the most critical factors in taking good CRP photographs, and perhaps one of the most difficult to control. The 3DMM autocorrelation process works very well for properly illuminated, high-contrast areas. However, areas of low

contrast and uniform color, areas with high relief displacement, or areas that are obscured (by deep shadows or other features) can lead to mismatching and poor terrain correlation. One of the biggest causes of poor photos is inconsistent light caused by shadows. Shadows can be created by features of the subject that you are documenting or cast by features outside the area of interest (such as your head). When photographing out-of-doors, choose a time of day when shadows are minimal. This may occur when the sun is directly overhead.

The resulting photographs may not emphasize the subject visually; however, properly exposed images taken in full sun have outstanding results during autocorrelation. Use proper camera settings to ensure photographs taken during full sun are not overexposed. Other times of consistent lighting can occur on overcast or cloudy days, or when the subject is in full shadow. In these instances, it may be necessary to slow the shutter speed or use a tripod to ensure that photographs are not underexposed. Keep in mind that lighting and weather conditions can change quickly.

When shooting indoors, make sure the area is as well lighted as possible. Take a few test shots and examine them to make sure that images are not underexposed or blurry. Indoor illumination can be a problem and it may be necessary to slow the shutter speed or use a tripod to ensure that photographs are properly exposed. Using the flash function of the camera is not a good option, as it can cast odd shadows and flares that fall differently through successive stereo pairs, thus affecting autocorrelation. However, stationary light sources such as floodlights, which evenly illuminate the subject, may be necessary in

very low light conditions. When setting up lighting, make sure to provide adequate room around the subject for taking a complete set of stereophotos.

Filling the frame with the subject is also crucial. For small CRP projects, it may be most straightforward to observe the subject through the viewfinder to best determine camera height and overlap. When photographing a larger project or when oblique orientations are necessary, remember to center your subject in the frame. There is often no need to ensure the horizon or other points of reference are in every frame, especially if they detract from the subject that is being documented.

Camera Settings

The 3DMM software used for close-range photogrammetry documentation supports a great variety of cameras. Therefore, it is beyond the scope of this document to list each setting on each camera that could possibly be used for CRP documentation. The following should serve as a general checklist and reminder of settings to check for and should aid in avoiding pitfalls. However, it is important that the operator be familiar with the camera to be used for CRP and with the results that will be produced as settings are manipulated.

Focal Length and Distance

The settings that most dramatically affect success of the CRP project are the focal length (lens or zoom length) and focus distance. A fixed focal length lens makes this process most efficient; however, the zoom capability of multifocal length lenses can be an asset in variable field conditions as the camera lens system may be zoomed or focused to any setting that is appropriate for capturing project detail. However, it is necessary to perform the camera calibration and conduct the project at the same focal length and focus distance. A streamlined

approach for multifocal length lenses is to zoom to either the minimum or maximum extent of the lens and set the focal distance to infinity. Use tape with a minimal amount of residue, such as painters tape, to fix the lens in position.

For cameras that allow the operator to switch freely between autofocus and manual focus, the following produces effective results: Hold the camera at the height or distance at which you will be shooting or mount it on the tripod. Turn the control to autofocus and take a shot. Check that the distance registered on the lens is accurate and check the LCD (Liquid Crystal Display), or download the image to make sure it is in focus. Then switch to manual focus and tape the lens ring to make sure it does not move for the session in which you will be shooting at that constant distance.

Focus Weighting

Many cameras allow you to dictate how the appropriate focus is determined. For example, the camera may take readings from the center of the field of view, average readings from a number of locations, or take continuous readings. It is important to take several test shots and vary the mode of determining the autofocus to ensure that the appropriate focus is achieved for a particular situation.

Aperture

Set the camera on aperture priority. An aperture of f8 (or 35 mm equivalent) is recommended for CRP, as this provides a good depth of field. Proper depth of field ensures that the entire subject is in good focus, which is important for image matching. When shooting at a close distance to the subject, it may be necessary to increase the aperture to f11 or stop down the aperture to get the best depth of field. Refer to your camera manual or digital photography guide for a thorough discussion of aperture and depth of field.

“Film” Speed

The sensitivity of the sensor to light is defined by the International Organization for Standardization (ISO; http://www.dpreview.com/learn/?/Glossary/Digital_Imaging). The ISO setting affects the amount of light that the sensor will absorb during a defined period. The ISO range of a camera is dependent on a number of factors and it is helpful to consult the camera manual when setting the ISO. In general, the brighter the lighting conditions the lower the ISO. When shooting outside on a bright, sunny day, an ISO of 100 (or even lower if supported by the camera) is appropriate. In low-light situations, it may be necessary to increase the ISO to compensate for the aperture setting of f8. It is possible to get graininess or artifacts when the ISO has been pushed too high. Testing for the optimum ISO is important in low-light conditions.

Shutter Speed

While the shutter speed will be determined automatically by the camera once the aperture and ISO have been set, it is a good idea to be aware of the shutter speed. A shutter speed of at least 1/200th of a second is required for handheld photography. For lower shutter speed, adjusting the ISO or mounting the camera on a tripod may be necessary. Should there be camera motion from the wind or an unstable platform (such as a ladder), high shutter speeds (more than 1/1,000th of a second) may be necessary.

File Format

If possible, set to a combination of RAW + FINE. If not, set the file format to RAW if available; otherwise, set to the highest quality .tif or .jpg possible.

Image Rotation

Turn this setting off. The photo orientation must be known with respect to the camera and lens. Automatic image rotation will rotate the image 90° clockwise or counter-clockwise. At first, this may not seem like it would cause a problem, but experience has shown otherwise. When taking nadir photos, it is sometimes impossible to tell which way the camera was rotated when the picture was taken. This can easily happen if photos are taken on opposite sides of a subject with no horizon in the view. The camera calibration cannot be applied correctly if the original orientation is not known.

File Naming

Most digital cameras provide the option to customize the file name or numbering template. Two basic options are the continuous numeric incrementing of file names and restarting the numbering sequence each time the memory card is reinserted. Consecutive numbering is the best option, as it helps to ensure that image files are not overwritten during download. In addition, duplicate file names may be a problem when processing several sequences of images together in the same project.

Custom Settings

As digital cameras advance, so do the options for settings that are tailored to a specific brand of camera. These settings include auto sharpening, white balance, vibrating of the sensor to dislodge dust particles, and others. Once again, it is strongly recommended that time is taken to experiment with how each of these settings, will affect image quality and usability in a CRP project. In most instances (especially image sharpening, stabilization, and sensor vibration for cleaning), it is important to turn off these options.

Objects of known length, with circles at a calibrated distance and circular barcodes, surround a 1-meter-square area of biological soil crust in the Dry Creek Basin near Montrose, Colorado.

Appendix D

Conducting a CRP Project

To take useable stereophotos, some procedures must be followed. By adhering to these procedures, quality photos and efficient processing of those photos is ensured. In general, the steps to be followed are the same regardless of the camera or subject being photographed. However, certain circumstances will require flexibility and ingenuity, which comes with experience.

Close-Range Photogrammetry (CRP) projects can be placed into one of two categories—small (simple) and large (complex). Large projects are those with an area of interest greater than 5 m² or where complexities of terrain or access add to the level of expertise needed for planning and execution of the project. Projects that fall into this category may require a preliminary site visit or the inspection of overview photographs taken of the area. In some instances, the needed vantage points for capturing imagery may not be present, necessitating alternatives to ground-based capture, such as the use of a large ladder, aerial blimp, unmanned aerial system, or other type of elevated platform. Whereas the same basic procedures and equipment apply to both small and large projects, it would be difficult to address all the complexities that could arise with large projects and is beyond the scope of this document.

Small projects have an area of interest equivalent to or smaller than about 5 m². This type of project may also be referred to as extreme close-range as high precision of data points is expected. Design and image acquisition for small projects may be successfully carried out by resource specialists in the field. An overview of the procedures for small or extreme CRP will be provided in this appendix.

Project Planning

The first step in project planning is to establish the need for capturing 3D data of a subject and the detail and accuracy at which the data must be captured. Because of the versatility of the CRP process, the images needed for 3DMM process can be easily captured. This provides great flexibility in the subjects and uses for 3D data. Examples of data capture and use include the establishment of plots for vegetation or erosion monitoring, baseline capture of a feature, taking measurements of a delicate subject that can (or should) not be touched, and dense surface capture for hardcopy reproduction.

Because of the flexibility of the CRP technique, it is possible to obtain high accuracy 3D data from subjects that are at almost any orientation with respect to the camera position. Documentation can be conducted looking straight down at the ground, looking straight ahead at a rock art panel or historical structure, looking at a hillside from an oblique angle, or looking overhead. In all these instances, the same basic principles apply. It is important to get the plane of the sensor and lens parallel to the subject, to maintain a consistent height (or distance) from the subject, to ensure the subject has consistent illumination, and to make sure there is an object of known length in at least three images. To streamline the following discussion, it will be assumed that the camera is facing straight down at the subject. If this is not the situation, camera distance can be interchanged for camera height.

In general, the subject of 3D documentation falls into one of two categories based on the size of the feature to be captured.

Either it is small enough that it may be captured in its entirety (such as a rock art panel) or it is so large that only samples of the area can be economically captured (such as soil erosion monitoring plots). These subjects are referred to as predetermined and sample, respectively. Predetermined subjects are specific features that are to be documented, such as a dinosaur track, historical structure, specific erosional feature, or something specific that must be measured. Sample features refer to situations where there is a defined area to be studied, but the exact site of the CRP project can be selected within that area. An example would be the establishment of a plot for erosion, vegetation, or other types of monitoring. The following section makes recommendations for establishing a sample monitoring plot.

Sample Plot Establishment

For areas as large as 5 m², stereoscopic images with a GSD of 0.5 mm are easily achievable. For most applications, this would provide a suitable level of 3D documentation. It is, therefore, necessary to determine the size of the plot. Depending on the study to be undertaken, the size can vary from 0.5 × 0.5 m² to a rectangular area of 1.0 × 5.0 m. It is recommended that sites be selected with different geomorphic characteristics. Keep in mind that vegetation can have an effect on the density of 3D data collection. This can result from plant movement caused by wind during successive stereophoto acquisition or by simply obscuring the ground. Choosing a site with minimal vegetation would be optimal; however, information may be gained by selecting sites with varying vegetation types, heights, and percentages of ground cover.

Choose a location where the effect on the site can be limited. Try not to step or walk within the sample area, especially if the activity will affect the results of the study. If the CRP is going to be repeated over

successive intervals, it is important to place monuments, such as survey nails or rebar (if appropriate), at the four corners of the site and at least one additional point in the middle of each side, for a total of six monuments. Longer plots should have additional monuments along the sides (one every 1.5 m is suggested). The monuments should be driven flush to the ground to minimize movement. File the top of the rebar to smooth the top surface and the edges. Make sure the top of the rebar is as smooth as possible. Monuments should have a small center point punched into them for exact positioning or marking. It is important that the monument be visible in the stereo sequence. To ensure ease of location it is helpful to place a circular object over the rebar. A compact disk (CD) that has been spray-painted white works very well. It is important to ensure that the rebar used is small enough to fit snugly inside of the hole in the CD. If a number of plots are to be established, it is important to consider both the amount of time required to travel between sites, as well as setup time.

Predetermined Sites

For projects in which the subject is predetermined, the size of the area to photograph will be dictated by the extent of the feature. Deviations from this may occur when the feature is larger than 5 m², and only a portion of it will be documented. In this instance, it is necessary to choose an area that will provide the most representative information for the entire site. Although the long-term goal of the documentation may be monitoring, it is not always permissible to mark many subjects (such as cultural resources) with a monument. In these instances, selecting unique, photoidentifiable natural features as reference points may be necessary, and the use of high-accuracy GPS to relocate established control points over time may be required.

Photo Layout

Once the size and area of interest have been established, the next step is to determine the most effective photo layout. It is important to strike a balance between the level of resolution needed, completely covering the area with overlapping stereophotos, setup time, and processing time. Two approaches can be taken—one minimizes the number of photos needed

and the other sets out to achieve a particular resolution.

Several examples (Figures D.1, D.2, and D.3) illustrate the layouts that can be used for CRP, including single strip and block layouts. When preplanning a photo layout or doing so on an ad hoc basis in the field, it is important to maintain a consistent height and 60% overlap for good stereoscopic photographs (see Appendix A).

Figure D.1. A small subject requiring a single stereo pair. When needed, an identification (ID) sheet can be placed in the first frame of the stereo sequence, to the left of the area of interest. ID sheets are helpful when photographing a series of subjects that have reference identification codes, such as monitoring plot numbers or museum catalogue codes. The date, weather conditions, photographer, and other types of information can be added to the ID sheet.

Figure D.2. Photo layout for a single strip of overlapping stereoscopic photography. A single camera is used to photograph each image in succession by moving from one camera position to the next. Note that control points are only necessary when tying photographs to an established reference, such as real-world coordinates or a monitoring datum. An object of known length or calibrated control stick is always necessary.

Figure D.3. In some instances, the size of the subject may dictate that two or more lines, or strips, of photography are needed to completely capture the subject in stereo. In these instances, a block approach is taken. For a block it is necessary to maintain about 20% sidelap between strips. Control points in the sidelap area are useful. This figure uses low-level aerial images from the Powder River Monitoring project to illustrate overlap and sidelap for block setup.

Camera Calibration

Camera calibration photographs must be captured at the same settings as the stereophotos. This can be achieved by simply taking at least two additional photos turned 90° to the previous photos and two additional photos turned 270° to the previous photos (Figure D.4). This is easily accomplished by adding two additional photographs at the beginning or end of the stereo shots. The main purpose of the

camera calibration is to determine and map the distortions in the lens with respect to the sensor location. The software accomplishes this most effectively when there are a large number of autocorrelated points in common between the stereoscopic images and the additional 90° and 270° photos (Figures D.5 and D.6). In some instances (such as a strip of only a few models), it may be desirable to recapture the entire strip at 90° and 270°.

Figure D.4. The camera calibration process requires at least four additional photos. By concentrating the previously taken stereoscopic photos (landscape) and portrait-oriented photos taken at 90° and 270° over the same area, maximum benefit will be achieved in the camera calibration portion of the software.

Figure D.5. To ensure project accuracy, it is necessary to take additional photographs to be used in the camera calibration process. These photos are taken at right angles, or 90° and 270° , to the sequence of stereoscopic photos and **MUST** use the same settings (particularly focus and focal distance). At least four photos are needed and should be stereo pairs. They may be taken at any position in the stereoscopic sequence as long as they are in common with it. At least one stereo pair must be taken with the camera turned at 90° , and then the camera should be turned 270° with another pair of photographs taken at a slightly different location.

Figure D.6. Camera calibration photos for a block setup. In addition to the camera calibration, images taken in the above configuration can serve to tie the two strips together and improve accuracy (Figure D.3).

- object of known length

Photo Control

Another level of flexibility provided by CRP over traditional photogrammetry is in the way a subject may be controlled. Control for a user defined coordinate system can be accomplished as simply as adding an object of known dimension (meter stick, 6-inch scale, or other object) that is visible in at least two stereo models. This allows the subject to be scaled to real-world values. It is preferable to have two or more such objects, to ensure that they are visible in at least three photographs and for accuracy assessment. Experience has shown that an object of known dimension is more accurate and reliable than measuring between two points in the field. However, measuring and recording the distance between two or more points is another excellent means for confirming project accuracy.

Calibrated target sticks (CTS) may be used in addition to the object of known dimension (Figure D.7) to provide extra control, and in some instances, can help tie photos together during processing. The CTS depicted in Figure D.7 are equipped with large, black circles that are a calibrated distance apart. In addition to the calibrated circles, a series of circular bar codes (Forbes et al. 2002) can be generated within some

Figure D.7. Examples of calibrated target sticks (CTS) and an object of known length. The center CTS contains circular bar codes, which are used by some three-dimensional measuring and mapping software and assist with the initial image orientation process.

3DMM software. Each unique code can be recognized, correlated to the same code visible on other photographs, and marked with very little user interaction. If coded targets are not available, solid color circles of high contrast to the background (black on white) can be used by subpixel marking methods to define the center of a circle.

To tie the CRP project into a real-world coordinate system, GPS positions for known points within stereo overlap are necessary. For monitoring or other studies that require a time sequence of image capture, it is beneficial to get high-accuracy horizontal and vertical coordinates from an RTK GPS. The GPS coordinates should be taken at the monumented points; additional coordinates can also be captured for other photo recognizable features to strengthen the resolution and for accuracy checking. For projects in which location is not as critical, a resource grade GPS unit may be used and point coordinates taken at the CTS circles.

Other Considerations

Context Photos

While capturing the stereoscopic photos, it is also helpful to take an overall contextual photo (yes, you can include the horizon). It helps to remind you of how things were set up and can be used as an interesting illustration (Figure D.8). Also, make sure to get some photographs of the photogrammetric documentation in progress (Figure D.9). It is preferable to have a secondary camera (this can be a point-and-shoot), which allows photographs to be taken without disrupting the focus or settings of the primary camera.

File Management

File management is extremely important. The digital age has advanced us to where the acquisition of photographs is practically free. With the help of 3DMM softwares, photos can be used to make quantifiable measurements, transforming them from

just pictures to data. Stereophotos may be used for data extraction the day they are taken, or years later. To ensure that these photos are still accessible, it is recommended that a consistent approach to file management be taken.

One strategy is to group files into directory structures that are organized by State or field office, site, date, and then by camera or lens, for example:

UTMoab/date/nik25/photos.tif

This may seem unlikely, but getting more than 10,000 close-range photographs may take a relatively short time. One of the values of the photogrammetric techniques is that photographs taken from the past (or future) can be incorporated into a project so that sites can be compared and monitored for change detection. For some projects photographed over multiple years, those digits can add up quickly.

Figure D8. The results of merging a contextual photo with the camera locations generated in the three-dimensional measuring and mapping software are very good for displaying image relations. (Camera stations are depicted above the surface as blue rectangles and the image prints are depicted as blue and green Xs on the surface.) The image highlights locations of extreme close-range photogrammetric documentation at the Twentymile Wash Dinosaur Tracksite, Utah.

Figure D9. Work in progress at a camel trackway on BLM land near Santa Fe, New Mexico.

Preparing to take a single sequence of overlapping photographs at the Red Gulch Dinosaur Tracksite in Wyoming.

Project Workflow

The following section is a general workflow for a small project. It is presented in outline form to serve as a guide and

checklist. As the photographer becomes more familiar with the process, this list can be tailored to his or her experience and specific project requirements.

General Procedures for a Small, Close-Range Photogrammetric Project

- Evaluate subject and establish extent of the area to be photographed.
 - Assess public interactions. When working at a site visited by the public, it may be necessary to have an additional person to act as docent. This person can serve the dual function of reducing the effects of visitors on the photogrammetric process and explaining the photogrammetric work to the public.
 - Temporarily mark the area to be photographed.
 - If necessary, prepare the site by removing extraneous debris or objects that may be obscuring the terrain to be measured.
 - Sweep or clean, if hard surface. Proceed with care when documenting fragile or protected subjects!
- Determine the sun angle and best location to stand or position the tripod without casting shadows onto the subject.
- Establish final extents of project area.
 - If appropriate, place a monument with survey nails or rebar while disturbing as little of the area as possible.
 - Place CDs over each of the rebar monuments. (CDs should be painted with flat white paint). The CDs will obscure some of the sample area; however, the ground will already have been locally disturbed.
- Lay target sticks parallel to a long side, just outside the sample area.
 - Follow the photo layout (Figures D.1, D.2, D.5, and D.6)
 - Do not obscure features or control.
 - Position the target sticks along the side that the photographs will be taken from.
- Set up the tripod; attach the boom arm and add counterbalance weights to the legs, if necessary, to offset the camera if working on a slope. Set the tripod to proper height.
- Fill out the site recording sheet
 - Date
 - Site ID
 - Record next photo number.
 - Place the recording sheet clipboard on the ground outside, but near, the site.
- Set the camera to the appropriate settings (see Appendix C). Change the ISO, if necessary, for light conditions.
- Mount the camera on the tripod, adjust height, and ensure that the proper overlap is achieved.

- Set the camera to autofocus, take a picture, and inspect it for quality—focus, exposure, and other characteristics. Make adjustments as necessary.
- Once the focus is set, turn the camera to manual focus and tape the focus ring in place.
- Proceed systematically from left to right along the length of the site and take as many photos as necessary to ensure complete stereo coverage.
 - To maintain a proper 60% overlap, the camera must be moved a distance equivalent to 40% of a single photo field of view (Figure A.2).
 - Remember—the entire area must be covered by at least two overlapping photos, this will require positioning the left extant of the project in the first frame of the sequence.
- In order to create a camera calibration, take additional photos turned 90° and 270° to the previous photos:
 - At the end—turn and take a picture of the end of the site. Camera will be turned 90° and 270° to the site.
 - Go back to the start of the site and take a picture. Again, camera will be turned 90° and 270° to the site.
 - Additional 90° and 270° photos can be captured anywhere along the strip.
- When conducting several small projects in sequence, it may not be necessary to change focus or camera settings if the height remains constant. In this situation, it is helpful to have a sight recording sheet in the first image of that sequence.

If possible, download photos and inspect for proper exposure and overlap before removing target sticks or CDs positioned on GPS control.

- Back up images (including RAW files) onto DVD or external hard drive.

Equipment Check List

- ___ People
 - ___ Person to take photographs
 - ___ Assistant to prep the site and keep track of work progress
 - ___ Docent to interact with public (may be needed at visited sites) and take photos of documentation process
- ___ Camera and lens for CRP documentation
- ___ Secondary camera for backup and to document CRP process
- ___ Camera Accessories
 - ___ Battery charger or extra batteries
 - ___ Additional lenses equipped with protective bypass filters
 - ___ Painter's tape or other low-adhesive tape
 - ___ Spare memory cards
 - ___ Remote shutter release
 - ___ Lens cleaner or brush
 - ___ Padded camera case
- ___ Laptop Computer
 - ___ Card reader or appropriate cable for downloading images
 - ___ Image backup—either portable hard drive or blank DVDs
 - ___ Image software (preferably the software that came with the camera)
 - ___ Power cord
 - ___ DC adapter (if available)
- ___ Objects of known dimension
 - ___ Commercial meter (or yard) sticks
 - ___ Calibrated target sticks of varying lengths (see Figure D.8)
 - ___ Removable adhesive putty may be used for temporarily securing target sticks, although even this may not be appropriate for some delicate surfaces.
- ___ Sturdy Tripod
 - ___ Boom or extension arm
 - ___ Quick release head
 - ___ Extra release plates
 - ___ Small screwdriver
 - ___ Leg weights for camera counterbalance to keep the tripod from tipping over
- ___ When Establishing Location
 - ___ GPS unit
 - ___ Resource grade or RTK system (depending on desired product accuracy)
 - ___ Survey nails or rebar
 - ___ Sledge hammer, small chisel, and file
 - ___ CDs spray-painted white
- ___ Power Accessories
 - ___ Multiple-receptacle power strip
 - ___ DC power inverter for car use
- ___ Miscellaneous Items
 - ___ Measuring tape
 - ___ Notebook and pencil
 - ___ Pocket calculator
 - ___ Small dry erase board or clipboard with identification sheet and markers
 - ___ Circular disks (such as clay poker chips) to mark features or image extents
 - ___ Step stool or ladder
 - ___ Small tarp for shade or wind protection
 - ___ Rope
 - ___ Duct tape
 - ___ Wisk and push brooms (when appropriate)
 - ___ Tree loppers or pruners (when appropriate)
 - ___ Pin flags or flagging tape

AERIAL PHOTOGRAPHS IN GEOLOGIC INTERPRETATION AND MAPPING

By RICHARD G. RAY

ABSTRACT

Aerial photographs today are widely used to obtain both qualitative and quantitative geologic information; vertical aerial photographs are used almost to the exclusion of other types. Techniques and procedures described herein relate primarily to vertical photography.

Geologic interpretation of aerial photographs is based on the fundamental recognition elements of photographic tone, color, texture, pattern, relation of associated features, shape, and size. The scale of photographs, as well as the vertical exaggeration that is present in most stereoscopic models, also are significant in photointerpretation.

The amount of geologic information that may be obtained from aerial photographs is primarily dependent on the type of terrain (igneous, metamorphic, or sedimentary), climatic environment, and stage of the geomorphic cycle. Because features are more readily recognized where strong differences exist in the erosional resistance of adjacent rocks, sedimentary terrain may be expected to yield the greatest amount of information from aerial photographs. Metamorphic terrain may yield the least information because metamorphic processes tend to destroy differences that may have existed in the unmetamorphosed rocks. Combinations of criteria such as photographic tone, texture, pattern, and vertical exaggeration permit inferences as to rock type and geologic structure, which are important in petroleum exploration, ore-deposits search, and engineering geology.

In petroleum exploration aerial photographs provide a wealth of information primarily with regard to potential structural traps. Folds commonly may be interpreted from a study of strike and dip of bedding and from stream patterns; anomalous stream characteristics, such as stream deflections, may suggest subsurface structures. The variety of photorecognition criteria that suggests faults permits aerial photographs to be of particular use in many ore-deposits studies. Analysis of soil patterns yields information regarding permeability of the surficial materials that are a concern of the engineering geologist.

The instruments used for viewing photographs, measuring geologic features, and compiling geologic maps range from simple stereoscopes and stereometers, or measuring bars, to complex double-projection instruments such as the multiplex or Kelsh plotter. Some instruments require the use of paper prints; others require the use of glass-plate diapositives. Measuring devices primarily provide spot heights or differences in altitudes; these quantitative data may be geologically significant in measurement of stratigraphic thickness and dip of beds and in structure contouring. Accuracy of vertical measurements is related fundamentally to the scale of photography and the instruments used for making measurements. In general, accuracy of measurement is greater

when large-scale photographs are used and when double-projection instruments rather than simple parallax bars are employed.

INTRODUCTION

Use of aerial photographs to obtain geologic information—popularly called photogeology—has contributed to mineral and fuel discoveries, and to engineering geology studies, as well as to the general geologic mapping of many areas; it also has increased the efficiency of many geologic mapping groups by adding speed, economy, and accuracy to areal mapping as well as adding certain geologic information that is impossible, difficult, or economically impractical to obtain by routine field-mapping methods. The past financial success of consultants in geologic interpretation of aerial photographs attests to successful geologic application of photogeologic procedures and techniques, particularly in petroleum geology, and to lesser extent in mining and engineering geology.

Many technical papers on the geologic interpretation of aerial photographs have been published, primarily since the end of World War II; on several occasions symposia on photointerpretation, and specifically photogeology, have been presented. Much of the information currently available has been published as individual articles and they are scattered throughout the literature; comprehensive treatments on the geologic interpretation of aerial photographs are generally unavailable now (1959) (see Eardley, A. J., 1942; Smith, H. T. U., 1943b; and Petrusevich, M. N., 1954). In addition to the published information much unpublished information also has accumulated in recent years. The collection and synthesis of much of this information, together with discussion of photointerpretive and related photogrammetric procedures, are the main objectives of this paper. The paper is particularly intended as a guide to geologic interpretation of aerial photographs as applied as a tool in reconnaissance geologic mapping, and as a reference to published papers representative of the photogeologic literature.

The primary objectives of photogeology are (a) to contribute to geologic mapping, which in turn is basic to mineral and fuel exploration, engineering geology studies, some water-resources investigations, and related studies, and (b) to contribute to geologic knowledge through research. The objectives of photogeology may be economic or academic, and procedures used can be expected to differ widely, ranging, for example, from use solely of simple lens stereoscopes for qualitative interpretation to employment of precision stereoplotters for making geologic measurements. Regardless of procedures used, however, photogeology to date has contributed principally to the broad aspects of geologic study, that is, in mapping distribution of rock types and structures. The interpreter can only infer the composition of rock types from photographs; he cannot identify mineral types or absolute ages of rocks. Thus, maximum use of photogeologic procedures is attained by combining photogeologic studies with various laboratory studies and with field investigations.

The uses of aerial photographs and the various photogeologic procedures are discussed herein under the general headings of interpretation and instrumentation. The part dealing with interpretation is widely illustrated with stereoscopic pairs and triplets, single photographs, and mosaics, together with explanatory notes, to demonstrate the kinds and amounts of geologic information that can be obtained from aerial photographs of differing geologic terrains and to illustrate some uses of photographs in specific studies, such as the search for petroleum. These photographs demonstrate primarily the qualitative uses of the fundamental recognition elements in geologic interpretation; they represent only a sampling of the tremendous number of illustrations available. Because reproduction processes tend to obscure details only subtly expressed on aerial photographs, selection of photographs used in this paper was confined principally to those that illustrate clearly defined recognition elements and geologic features. All aerial photographs (figs. 39-114) are at the end of the paper. Agencies holding the negatives of these photographs are given in a list that follows the photographs.

Methods and significance of determining quantitative geologic information from aerial photographs are described under the heading of instrumentation.

THE AERIAL PHOTOGRAPH

The aerial photograph is an instantaneous record of the ground details as determined chiefly by the focal length of the camera lens, the flying height of the airplane at the time of exposure, and the film and

filters used. It may also be defined as a composite of photographic images, which make up the recognition elements used for interpretation. The aerial photograph is a perspective photograph that is geometrically related to the type of camera in which it is taken; it may be a vertical photograph, taken with the camera axis pointing essentially vertically down, or it may be an oblique photograph, taken with the camera axis purposely tilted from vertical, generally 20° or more. Vertical photographs currently are used almost to the exclusion of oblique photographs for geologic interpretation, and most photogrammetric instruments used in photogeology in the United States are designed to accommodate vertical photographs; hence the following discussion is limited to techniques applicable to the study of vertical photography. Twin low-oblique photographs—those in which the apparent horizon is not shown—generally may be transformed and the resulting paper prints used as vertical photographs; however, low-oblique photographs cannot be used in many stereoplotting instruments unless the instruments are specially designed.

A general knowledge of the geometry and terminology used with vertical aerial photographs is necessary if one is to understand and make maximum use of photographs for interpretation and mapping purposes. The terminology and geometry of the vertical photograph are presented in figure 1.

FACTORS THAT AFFECT THE PHOTOGRAPHIC IMAGE

Factors that affect the photographic image, and hence interpretation, may be divided into two groups: (a) The relatively constant man-controlled factors, such as focal length of lens, flying height, film and filter combinations, and lens angle; and (b) the variable natural factors including color of objects photographed, position of an object with respect to the angle of sun, amount of haze in the atmosphere, and others. The constant factors are discussed briefly below; effects of natural factors on the photographic image are described where appropriate throughout the text.

FOCAL LENGTH AND FLYING HEIGHT

Focal length and flying height may be considered together because of the relation of photograph scale to these two factors. In terms of focal length and flying height, the average scale of a photograph is expressed as

$$S = \frac{f}{H}$$

or

$$\text{Scale} = \frac{\text{focal length (feet)}}{\text{flying height (feet)}}.$$

FIGURE 1.—Geometry of the vertical aerial photograph.

Thus, for example, the scale of photographs taken at 10,000 feet above mean terrain with a 6-inch (0.5 foot) focal-length lens is

$$\frac{0.5}{10,000} = 1:20,000.$$

It is evident that as focal length increases, the scale of photographs becomes larger, but as flying height increases, scale of photographs becomes smaller. Therefore, at any given flying height, long-focal-length lenses result in larger scale photographs than short-focal-length lenses. It follows also that at a given flying height a greater number of photographs are necessary to cover a given ground area when long-focal-length lenses are used. Doubling the focal length of the lens, for example, will quadruple the number of photographs required to cover a given area at a given flying height.

It should be noted that if a photograph is enlarged or reduced, the "effective" focal length for that photograph is also changed in direct proportion to the amount of enlargement or reduction. Thus, if photographs taken with a 6-inch-focal-length lens are enlarged two times, the effective focal length is changed from 6 inches to 12 inches. Parallax measurements (see p. 53), used in determining differences in altitude, are increased, but the absolute value for each unit of parallax measurement is decreased. Reducing or enlarging photographs thus has a significant effect with respect to choosing appropriate measuring and plotting instruments, and in measuring differences in altitudes.

For determining scale from the formula $S = f/H$ the effective focal length must be used where photographs have been reduced or enlarged. Particular note should be made in the use of transformed low-oblique photographs, in which the effective focal length is almost always less than the focal length of the camera.

FILM AND FILTER COMBINATIONS

The appearance of the photographic image may be controlled to marked extent by the sensitivity of the film and by the light transmission of the filter employed. The sensitivity of a film emulsion may be controlled when the film is manufactured so that all or only selected parts of the visible spectrum are recorded, or so that part of the invisible spectrum, such as infrared light, is recorded. Also, the wave length of light reflected from an object and actually recorded may be controlled in part by filter combinations. The recording of selected wave lengths of light, controlled by filters or type of film, or by combinations of film and filters, affects the photographic image, primarily by affecting the photographic tone. Conventional pan-

chromatic aerial film is generally exposed through a minus-blue filter and permits the recording of blue-green, yellow, orange, and red light. When color film is used the entire visible spectrum is commonly recorded and a greater number of color differences can be distinguished than on conventional black-and-white film. Special color film or color film used with filters may distort the color of the objects photographed, but if differentiation of geologic features is permitted, then lack of color fidelity may not be detrimental to interpretation. Ideally, film and filter combinations may be used to accentuate specific features for a given type of interpretation (see p. 7-8).

LENS ANGLE

The angle of the camera lens—that is, the apex angle of the cone of rays passing through the lens—is important indirectly in relation to radial displacement and parallax measurements, which are in turn significant with regard to photogrammetric applications in geologic interpretation. Characteristically, long-focal-length lenses (greater than 6 inches) have a narrower lens angle than short-focal-length lenses (6 inches or less). Thus, to maintain a given scale and format size, photographs taken with a narrow-angle (long-focal-length) lens requires flying at a higher altitude than with a wide-angle (short-focal-length) lens. Under these conditions, radial displacement (also termed "relief displacement") of similar image points is less when narrow-angle lenses are used, but only because of the greater flying height required by the narrow-angle lens to maintain the given scale and format size. The parallax difference for an object of specific height is in turn affected as a result of the difference in flying height, the parallax difference decreasing directly with increased flying height for a given focal-length lens (see p. 53). Thus it can be said that lens angle indirectly affects parallax measurement. When a constant flying height is maintained, however, lens angle does not affect parallax measurements of similar image points. Image distortion at the margins of photographs taken with a wide-angle lens may be greater than on photographs taken with a narrow-angle lens and this is considered by many to be detrimental to photointerpretation, especially in high-relief terrain.

VIEWING OF PHOTOGRAPHS

Photographs may be viewed singly, as mosaics, or as stereoscopic pairs. Most commonly stereoscopic pairs of paper prints are viewed in reflected light with simple lens, prism, or mirror stereoscopes, notes are made directly on the prints or on transparent overlays, and information is later transferred to a base map or

mosaic. Many paper prints can also be viewed with transmitted light, which may be helpful in revealing photographic detail. If vertical measurements are made from paper prints a separate measuring device must be commonly employed with the stereoscope. In recent years double-projection instruments, employing the anaglyph principle in forming the stereoscopic model from glass-plate diapositives, have been used increasingly in geologic interpretation.

When photographs are viewed singly or in a mosaic, a two-dimensional view is obtained. The single photograph or mosaic is normally viewed along a line generally perpendicular to the photograph surface, but for some subtle linear features, an oblique view of the surface with a reflected light source moved to different positions may reveal photographic details otherwise difficult or impossible to see (see Lattman, 1958, p. 575). Many valuable relations of geologic and associated features can be observed, particularly as a result of the overall view permitted by mosaics or single prints of small scale, but a two-dimensional view reveals only part of the data available to the interpreter; the value of three-dimensional, or stereoscopic, examination of aerial photographs in contrast to studying the two-dimensional view cannot be overemphasized. Conspicuous geologic features are commonly visible on single aerial photographs or mosaics of aerial photographs, but the wealth of information seen in stereoscopic view is many times greater. Details, such as fine lines or textural differences not readily seen on single photographs—or even on the ground—commonly are shown clearly in the stereoscopic model. Such clarity is in many places a direct result of the common association of fine lines and textures with relief changes, which are exaggerated in most stereoscopic models. To take advantage of the exaggerated vertical dimension, which is so helpful in photointerpretation, aerial photographs should of course be viewed stereoscopically. It may be desirable also to view the photographs pseudoscopically by reversing the print positions so that hills appear as valleys and vice versa. In pseudoscopic view, stream patterns or anomalies may stand out (see fig. 95), or because of the unnatural view other features may be accentuated. Aschenbrenner (1954, p. 401) demonstrated by the use of a seemingly random distribution of dots, which may be likened to silver grains of a photographic emulsion, that information not visible on a single picture can be clearly seen in stereoscopic view.

INTERPRETATION

Interpretation was defined broadly by Summerson (1954, p. 397) as the prediction of what cannot actually be seen; and thus geologic interpretation of aerial

photographs is not unlike certain geologic interpretations of field-observed data. Colwell (1952, p. 535; 1954, p. 433) defined interpretation as “* * * the act of examining photographic images of objects for the purpose of identifying the objects and deducing their significance.” However, geologic interpretation, more often than not, is a result of combined deductive and inductive reasoning, based on the principle of cause and effect. For example, certain features easily identified on aerial photographs, such as terminal moraines and kettle holes, are inductively concluded to have resulted from glaciation, and this in turn may lead by deductive reasoning to the specific identification of less readily recognizable features, such as certain kame terraces. Further deduction may lead to conclusions concerning the type of material present in these terraces. On the other hand, interpretation may be directed mainly toward understanding the geologic significance or history of a broad area, and specific features such as positions of beds and measurements of stratigraphic thicknesses combine by inductive reasoning to reveal the probable geologic conditions that resulted in those features.

Geologic interpretation of aerial photographs can be considered generally a two-step process. The first step includes observation, fact-gathering, measurement, and identification of features on the photographs. The second step involves deductive or inductive mental processing of these data in terms of geologic significance. According to Stone (1951, p. 755) a procedural or methodical approach to interpretation should be used because “The establishment of procedure prepares the way for orderly and complete analyses of complex subjects.” A procedural or methodical approach appears to be especially applicable to the observational phase of a photogeologic study, and it will give a firm basis on which the interpretive phase is dependent.

Observational data, also termed “first-order” information (see Hopkins, Karlstrom, and others, 1955, p. 142), may be subjected to either the empirical or rational method of processing (Smith, H. T. U., 1953, p. 9-10). According to Smith (1953, p. 9) the empirical process is largely mechanical rather than perceptive, and involves matching images of a photograph with similar reference images; reasoning is largely by analogy and this “Reasoning by analogy alone is notoriously deceptive, unless extreme care is taken to make certain that the analogy is truly complete.” Smith (1953, p. 9) also made the particularly significant statement that “Nature is not always so obliging as to provide the desired simplicity and uniformity of conditions” that would permit the ready application of empirical methods. Indeed, much in nature is com-

plex and nonuniform, many terrain features are poly-genetic, and thus interpreting the geologic significance of observational data is dependent largely upon a thorough understanding of the principles of the sciences that explain the observational data. "The physical conditions of a particular terrain change, and the adjustment to that change is a gradual one, allowing all manner of intermediate forms and combinations between the norm for the old situation and that for the new" (Summerson, 1954, p. 396).

Surface expressions of geologic features—the observational data—range from the very obvious to the very subtle. Sorting those data that are significant to a particular problem and properly relating these features one to another provide a measure of the ability of the individual interpreter. Where more than one plausible explanation of observational data is possible, the experience as well as the fundamental geologic ability of the interpreter become especially significant. Thus a rational processing of observational data will yield the most meaningful interpretive results. This does not imply that an empirical method of processing observational data, exemplified by the numerous photointerpretation "keys," may not yield satisfactory results in certain geologic problems and terrains, but the logical, scientific approach demands a rational processing of observational data, particularly where inferences based on subjective interpretations are required.

If observational data cannot be rationally interpreted, they may still be of some empirical value. For example, an interpreter may recognize two zones of vegetation on aerial photographs. Without knowledge of plant ecology, he may infer that a geologic contact exists between the two vegetation types. But a knowledge of plant ecology, permitting a rational interpretation, might well have allowed a further inference that one type of rock or soil was likely to be highly permeable in contrast with the other, thus revealing information with regard to certain physical characteristics of the rock or soil, which in turn may suggest something of the lithologic character. Thus " * * * the understanding of any particular terrain requires more than the knowledge of the geology * * *" (Summerson, 1954, p. 397). The greatest understanding will be by individuals grounded in the natural sciences and who understand, as a result, the various factors that contribute to a particular region. Because any geologic terrain is normally a complex that also includes features of fundamental interest to the botanist, forester, soil scientist, and others, photogeologic interpretation must take cognizance of these related sciences. The combined use of vegetation, soils, and geologic

features to interpret geology is an example of what has been termed the "convergence of evidence" principle (Colwell, 1952, p. 566).

Interpretation, then, begins with the observation, identification, and measurement of features on photographs. One of the most obvious features is that of landform, and it has been stated by Johnstone (1953, p. 265) that analysis of landforms constitutes the basis of photogeology. Smit Sibinga (1948) also pointed out the importance of landform, or geomorphic expression, in interpreting the lithologic character of rocks; but analysis of landform, however important, cannot be the complete basis for photogeologic interpretation, for there is additional "first-order" information such as vegetation patterns, soil patterns, and stream patterns; photogrammetric measurements also provide first-order data. Features other than landform may actually be more important for certain structural interpretations. For example, vegetation may grow along and mark the location of a fault. Thus, interpretation is based not only on landform but also on photographic tone differences, color differences, drainage patterns, erosion patterns, soil patterns, vegetation patterns, and any other surface expression of underlying geology. It is fundamental that photointerpretation is only applicable to those geologic features that do develop such surface expressions.

The many features of surface expression used in photogeologic interpretation are identified on the basis of recognition elements—characteristics of the photographs that result from the scale selected; the color of the rocks, vegetation, and soils of the terrain photographed; the kind of film and filters used; the processing of the film; and related factors. The most significant recognition elements are relative photographic tone, color, texture, pattern, and association of features. Shape is important in identifying many constructional landforms. Finite size as a recognition element for geologic interpretation has been used very little, although relative size is commonly considered by the interpreter. The increasing use of photogrammetry in geologic interpretation, however, portends an increasing importance for size, not so much as a recognition element in the usual sense of the word, but as an interpretation element (see p. 13). Shadows may help in distinguishing certain tree types, which in turn may have geologic significance.

INTERPRETATION FACTORS

RECOGNITION ELEMENTS

PHOTOGRAPHIC TONE

Photographic tone is a measure of the relative amount of light reflected by an object and actually

recorded on a black-and-white photograph; it is fundamental to all other recognition elements, except color. Tones on conventional photographs are usually shades of gray, but may be black or white. Because of the ability of the human eye to differentiate subtle tone changes, relative photographic tone is a significant asset in geologic interpretation of aerial photographs. However, photographic tone is subject to wide variation and there are limits to its usefulness as a recognition element because of the many factors that can influence it.

Photographic tone depends on light reflectivity, which in turn depends on location of an object with respect to the sun; thus the time of day and month of year are influencing factors. Haze strongly scatters light, particularly at the short or blue end of the spectrum and hence affects photographic tone unless corrective filters are used. Geographic latitude, angle of reflected light, sensitivity of film, light transmission of filters, and processing also may exert considerable effect on photographic tone. Hence a standardized tone scale (Daehn, 1949, p. 287) would appear to have little usefulness unless relative photographic tones on different photographs could be equated in terms of the tone scale. It is probable that the use of a densitometer to measure relative photographic tone in terms of the density of the negative would be a satisfactory measure of tone, even though many factors influence the density. Particularly in quantitative studies the use of a densitometer to measure relative photographic tone may prove very worthwhile in differentiating certain geologic features (Ray and Fischer, 1960).

Photographic tone, despite the many factors that may affect it, can be a particularly useful interpretation element; its usefulness depends on the problem under consideration and on how tone is used in conjunction with other recognition elements. For example, if the fracture pattern of an area were studied and it were known that a lush and dark-toned vegetation grew along the fractures because of concentration of moisture, the relative photographic tone probably would be a significant recognition element regardless of the limiting factors mentioned above. On the other hand, as a means of distinguishing between two types of trees that reflect similar amounts of light but which might signify differences in the underlying geology, photographic tone might be of little value unless used in conjunction with other recognition elements, such as crown texture.

Raup and Denny (1950, p. 120), in work along the Alaska Highway, considered photographic tone the least satisfactory criterion in identifying and interpreting vegetation. But Tator (1951, p. 717) consid-

ered tonal contrasts to be major keys for recognizing landscape features of low relief in the coastal region of the Gulf States, such tonal differences resulting mainly from soil and vegetation differences. Schulte (1951, p. 697) pointed out, with regard to pure stands of trees, that at large scales photographic detail is more important, but at small scales tone becomes relatively more important.

Because the analysis of photographic tone is highly subjective it has been suggested that photographic tone might not be as useful as other recognition elements in interpretation. Because of differences that may arise from position, angle of reflected light, processing, and other factors, Stone (1956, p. 125) stated that photographic tone in interpretation probably has been overemphasized. This is true if the factors that affect tone prevent photographic distinction of images that might otherwise be made. But if changes in relative photographic tone are present on a photograph, the interpreter should expect that these changes might be geologically significant. Indeed, photographic tone is probably the most used recognition and interpretation element, although it is generally used in conjunction with one or more other recognition elements. The absence of photographic-tone changes, as a result of processing and other factors, where such tone changes might normally be expected, does not detract from the possible usefulness of tone changes on other parts of a photograph. It merely suggests that the potential of photographic tone differences has not been accomplished for the photographs in question.

It is worthy of note that in interpretation strong tonal contrasts are generally desirable. Yet modern automatic dodging devices commonly used in printing photographs generally reduce overall tonal contrasts, although locally, as in darkly shaded areas or brightly lighted areas, automatic dodging may strengthen tonal contrasts. Because most aerial negatives are slightly lighter in the corners than in the center, hand dodging is commonly necessary if automatic dodging is not employed in making prints. However, undodged or hand-dodged prints are probably the best for general photointerpretation.

For special interpretation problems it may be possible to enhance tonal contrasts within a limited range of the tone scale by film intensifiers or other photographic processes, such as use of selected filters. Ray and Fischer (1960) used selected filters in photographing weathered samples of the Bernal and San Andres formations of New Mexico. The Bernal formation is a red thin-bedded shale and shaly siltstone; the San Andres limestone is primarily a grayish limestone. Spectral reflectance curves, based on spectrophotome-

ter studies, show significant differences for these two formations (fig. 2). Particularly at the short or blue end of the spectrum a strong difference in intensity of reflected light is present; the San Andres limestone reflects almost twice as much light as the Bernal formation. A noticeable difference is also present at the long or red end of the spectrum. But the spectral reflectance curves of the Bernal and San Andres formations within 500 to 675 millimicrons—the wave lengths generally recorded on conventional black-and-white aerial photographs—show that the overall light reflectance from these two formations would average out to be generally similar and little photographic distinction should be expected within this range. It is significant that strong reflectance differences which exist in one part of the spectrum may be masked by reflectance characteristics in another part of the spec-

FIGURE 2.—Spectral reflectance curves of weathered samples of Bernal formation (red thin-bedded shale and shaly siltstone) and San Andres limestone (primarily a grayish limestone), New Mexico.

trum, and therefore to achieve photographic distinction of two features, it would probably be necessary to record a restricted part of the spectrum. Photographs of the Bernal and San Andres formations taken through filters that permit recording only of reflected light at the short or long end of the spectrum show a marked photographic distinction of the two formations.

COLOR

Color as a recognition element could be one of the most useful, if not the most useful, criterion for interpretive purposes (see Kent, 1957; Ray, 1958; Fischer,

1958; and Minard, 1960). The significance of differences within a photograph is interpretation and the greater the number of differences, such as color contrasts, the greater is the potential for detailed interpretations. It is a well-established fact that the human eye can differentiate about 1,000 times as many tints and shades of color as it can tints and shades of gray, characteristic of black-and-white photographs, and hence it may be concluded that color aerial photographs will permit a greater amount of detail to be recognized and interpreted. However, it is possible that two rock types of similar color might be differentiated more easily on certain black-and-white photographs than on color photographs because of mineralogic, chemical, or other differences that may permit significant contrasts in reflected light to be recorded when selected films and filters are used.

Petrusevich and Kazik (1955, p. 5, 8) reported that where color contrasts of rocks are not strong, boundaries between these rocks are more clearly seen on black-and-white photographs than on color photographs. Where color contrasts are strong, interpretation is facilitated in areas where individual beds are rather thick and the color of formations is retained for considerable distances along the strike. Petrusevich and Kazik (1955, p. 8) also reported that "A comparison of aerial color photographs of scales 1:15,000; 1:10,000; 1:8,000; and 1:5,000 for the same area, taken under the same conditions, shows that * * * the practical use of aerial color photography for geological purposes should be limited to a scale of 1:10,000 and larger." This conclusion was based on a study of photographs taken with an 8.25-inch lens. Recently developed short-focal-length lenses (3.5 inches and 6 inches) now permit useful color aerial photography to be achieved at a scale smaller than 1:10,000.

Aerial color negative film may prove particularly useful in photointerpretive studies. Unlike positive transparencies (reversible-type color film), which require use of filters during exposure of the film, negative-type color film is processed with filters inserted during the printing process. It is thus possible to vary the color contrasts through the simple medium of printing, with the possible advantages that certain features of geologic significance, such as alteration zones, may be emphasized. Petrusevich and Kazik (1955, p. 5) noted that a greater contrast often can be obtained in a black-and-white print from a color negative than in a print from the corresponding black-and-white negative. Fischer (1958, p. 546) in turn stated that black-and-white positive prints from Ektachrome aero positive transparencies also show stronger tone

contrasts between various rock units than the conventional black-and-white photographs.

TEXTURE

Texture was defined by Colwell (1952, p. 538) as " * * * the frequency of tone change within the image * * * [and] * * * is produced by an aggregate of unit features too small to be clearly discerned individually on the photograph." The scale of the photographs thus has an important bearing on this definition of texture. For example, a network of fine lines described as a texture on one scale of photographs may well be recognizable as a network of joints on a larger scale of photographs; this bears out Schulte's statement (1951, p. 697), made with regard to plant distribution, that at large scales photographic detail is more important, whereas at small scales tone becomes relatively more important. Such a texture, due to tone change within the image, may be called a "photographic texture" (figs. 43, 56, and 85). Photographic texture is therefore a comparative feature within any one general scale of photography. Although photographic tone is a fundamental element of photographic texture, the photographic conditions that affect tone may vary and yet permit such a texture to be a diagnostic recognition element. This is due to the fact that texture in the photographic sense is really a composite of several fundamental characteristics, namely photographic tone, shape, size, and pattern, and, of these elements, slight variations of tone would least significantly affect the recognition of a given texture.

Photographic textures have been described by various workers (Spurr, 1948; Raup and Denny, 1950) as coarse, fine, rough, and fluffy, but such descriptive terminology would seem to have very limited use unless accompanied by photographic illustrations. Furthermore, unless these descriptive terms are themselves clearly defined, comparisons of photographic textures with specific commonly known objects might be more useful. It may also be suggested that because photographic textures are normally considered as two dimensional, the use of a densitometer in conjunction with a coordinatograph-type instrument to determine tone changes per millimeter within the image might permit mathematical classification of such textures. However, such a classification might fail where a strong textural fabric prevailed, for two textures differing primarily because of shape or preferred orientations within the image might well be assigned to the same mathematical classification.

In addition to the use of the term "texture" as described above, texture has other meanings, as in reference to soils. The application of aerial photographs to soils and engineering geology studies has resulted in

the introduction of "soil texture" in some photogeologic literature; the obvious distinction between photographic texture, which can be directly observed, and soil texture, which must be interpreted from other recognition elements, must of course be made. Texture also has been used in relation to the density of a drainage network; wide spacing of streams results in a "coarse" texture of drainage and close spacing of streams results in a "fine" texture of drainage (figs. 3, 42, 49, 51, 62, 63, 79, and 106). Unless quantitative meaning is given to drainage texture, the term must be used on a comparative basis within any one general scale of photography. Horton (1945, p. 283-284) defined drainage density in quantitative terms but little use has been made of this classification by geologists.

Topographic texture has been used to describe the degree of dissection of the land surface (see Smith, K. G., 1950, p. 655-668). Like texture of drainage, topographic texture may be described as fine or coarse (figs. 39, 51, 62, 75, and 106). Quantitative study of topographic texture, based on map study, has shown that the texture ratio, a mathematical expression of the dissection of the ground surface, bears a logarithmic function relation to drainage density (Smith, K. G., 1950, p. 667-668). Therefore, because drainage density can be determined readily, aerial photographs may be useful in a comparative study of erosional topographies.

When texture is used to designate drainage density or erosional characteristics of the terrain, rather than to designate a photographic texture, the use should be so qualified as to make the definition clear. Although textures are commonly considered in terms of the two-dimensional plan view, it is important to note that erosional texture may well be significant or at least more readily recognized when viewed from the third dimension of the stereoscopic model (see fig. 39).

PATTERN

Pattern, as used herein, refers to the orderly spatial arrangement of geologic, topographic, or vegetation features. The spatial arrangement of pattern is normally considered by interpreters to be a two-dimensional or plan-view arrangement of features, but it may also be a three-dimensional arrangement. If features that make up a pattern become too small to identify, as on small-scale photographs, they may then form a photographic texture.

Patterns resulting from particular distributions of gently curved or straight lines are common and are frequently of structural significance; they may represent faults, joints, dikes, or bedding. But a single line, or lineation, is also an illustration of pattern; it

FIGURE 3.—Drainage map of large area in vicinity of ring dike shown in figure 54.

A separate tracing of drainage over a large area in the vicinity of the ring dike of figure 54 shows a marked decrease in drainage density within the ring-dike area. The contrast in drainage densities inside and outside of the

ring dike is more readily seen on a separate tracing of drainage than in the stereoscopic model. (See also fig. 9.) Inset shows area of figure 54.

may result from an orderly arrangement of stream segments, trees, depressions, or other features (figs. 74 and 84). This arrangement may be a continuous alinement of geologic, topographic, or vegetation features, but more commonly it is a discontinuous alinement. Because lineations are especially important as expressions of fractures they may indicate areas of considerable economic significance.

Drainage patterns are an important element in geologic interpretation of aerial photographs (figs. 48, 94, and 96). In bedrock areas these patterns " * * * depend for the most part on the lithologic character of the underlying rocks, the attitude of these rock bodies * * * and the arrangement and spacing of the planes * * * of lithologic and structural weakness encountered by the runoff" (Tator, 1954, p. 412). Stream patterns thus reflect the control exerted by underlying structure and rock type. But stream characteristics may be influenced by thickness and kind of surficial material where structural control is at a minimum. Under these conditions the drainage may reflect differences in surficial materials that are significant to the engineering geologist. (See Belcher, 1945, 1948; Jenkins, Belcher, Greeg, and Woods, 1946; Frost, 1946; Frost and Woods, 1948; Hittle, 1949; and Parvis, 1947, 1950.) In areas where resistance to erosion may be more or less uniform, as in many surficial deposits or in bedrock without pronounced structure, the drainage pattern is commonly dendritic or modified dendritic (see figs. 70, 77, and 106). Where structures are well developed, as in folded mountains, characteristic trellis, annular, or other drainage patterns may develop (see fig. 64).

Because the sensitivity of drainage to strike and dip directions is pronounced, changes in a drainage pattern, or deviation from an established norm, may be as important or more important than interpretation of any one stream pattern. "It is therefore important that relatively large areas be examined so that local drainage patterns [or anomalies] may be readily differentiated from regional drainage patterns" (Alliger, 1955, p. 180). A change in drainage may thus have significant structural implications (see figs. 9, 94, and 96). But a difference in stream pattern may also suggest variations in lithologic character of the underlying rocks.

Patterns of vegetation are also commonly of geologic significance and may reflect structural conditions or lithologic character of rock types (see figs. 40, 43, 54, 72, and 85). Woolnough (1934a, p. 213) suggested that a distinction be made between two types of vegetation distribution which he called "blocks" and "alinements;" the former occurs on extensive outcrops of

rock of uniform character, the latter along narrow rock bands, faults, or similar limited features. Alinements further may be subdivided as linear, parallel, and curved (see Woolnough, 1934a, p. 213). It is suggested that narrow linear or parallel alinements of vegetation may represent fractures (figs. 50, 60, 71, and 101), whereas wide, curved alinements may signify the distribution of outcrop of low, moderately or even steeply dipping beds (figs. 40 and 72); where curved alinements form closed loops they generally represent horizontal or nearly flat lying beds (figs. 61 and 77).

The term "pattern" has also been used in the literature in quite a different sense than described above. In the study of surficial materials the term "soil pattern"—a poorly chosen term—refers to the combination of surface expressions, such as landform, drainage characteristics, and vegetation, that are used in the interpretation of ground conditions (see p. 34–37). Thus pattern as defined above may be included as an element of the broad term "soil pattern," commonly used in engineering geology descriptions. Soil patterns may reveal information of direct use in engineering geology studies, as in the location of granular materials (figs. 52, 88, 104, and 108; and p. 34–37); in addition soil patterns may be important in suggesting the distribution of certain rock types; this distribution in turn may reflect geologic structures (see figs. 4, 48, and 81).

RELATION TO ASSOCIATED FEATURES

The relation of one feature to its surroundings is commonly important because a single feature by itself may not be distinctive enough to permit its identification. The significance of this relation may be spatial or genetic. For example, depressions may be identified as kettle holes because of their location near readily identified terminal moraines, and because of their genetic association with glaciated terrain. With regard to spatial association this recognition element has also been called the "site factor" (Colwell, 1952, p. 540); it may be particularly useful in determining the significance of vegetation with respect to the underlying geology. For example, certain tree groups growing on topographically high areas in interior Alaska suggest well-drained underlying materials. The landform, especially, in combination with the vegetation characteristics suggests stabilized sand dunes (fig. 56). The relation of associated features may thus permit specific identifications and inferences concerning surficial materials or rock types.

Photograph scale may be important in the interpretation of associated features; that is, a geologic feature on small-scale photographs may be interpreted because of its position with regard to other features,

FIGURE 4.—Generalized soil map of area shown in figure 48 (modified from soil survey map of Abbeville County, South Carolina).

The circular area underlain by Mecklenburg loam and Iredell loam is conspicuous. These soils delimit an area of mafic intrusive rocks from a surrounding area of silicic rock types. Particularly where outcrops are sparse or lacking, soil maps may provide significant geologic information, espe-

cially in areas of residual soils. The soil maps may provide structural or lithologic data with respect to underlying rocks, or they may provide pedologic data concerning the surficial materials that is useful to the engineering geologist.

all of which can be seen at the same time (fig. 55), whereas on large-scale photographs direct identification might be made because photographic details are visible. The usefulness of association as a recognition element also will vary not only with photograph scale but with the objective of the study. The engineering geologist may be confronted with the immediate identification and location of kames as a source of gravel near a proposed highway route, whereas the geologist mapping the entire area would be interested in the identification, orientation, and distribution of all kames, with respect to geologic history of the area.

SHAPE

Shape as a recognition element in geologic interpretation is significant primarily only in its broadest defi-

nition, which involves relief or topographic expression. In this regard shape is very important in recognizing constructional landforms, such as volcanic cones, sand dunes, river terraces, and certain glacial features (figs. 41, 55-58, 60, and 104); it is also useful in differentiating rock units where one formation is expressed in bold cliffs and overlies a second formation that shows a lesser angle of slope (figs. 62, 84, and 91), or where adjacent rocks show significant differences in topographic relief (fig. 65). Rectilinear depressions may be expressions of faults (figs. 60, 85, 86, 99, and 103). The general surface configuration, as in the "beehive" weathering of some massive sandstones, also may be regarded as an expression of shape that is useful in recognition. According to Belcher (1945, p. 140-141)

shapes of gully cross sections are important to the interpretation of surficial materials for engineering purposes. However, in its strictest definition, as "a spatial form with respect to a relatively constant contour or periphery" (Webster's New International Dictionary, 1950) shape has been of little importance as a recognition element because nature may reveal the same geologic feature in an infinite number of different shapes, and because common scales of photography (1:20,000) restrict an interpreter's ability to see details of shape. Where local field criteria have been established, shape may be useful, for example, in the interpretation of patterned areas (fig. 53) or in the study of gully cross sections, particularly when large-scale photographs are available (fig. 88).

Shadow as a recognition element is primarily a use of shape and photographic tone. Because vertical aerial photographs are commonly used for interpretation, shadows may permit an effective side view of some features. For example, shadows may be useful in interpreting tree types, such as conifers, which generally have pointed tops; the type of tree in turn may have a relation to underlying geologic materials and particularly to soil-moisture conditions (Stoeckeler, 1952, p. 4). For interpreting most natural features, however, the shape of shadows probably contributes little in direct identification. Insofar as shadows contribute to textures and patterns, they are of course of great importance. Even slight topographic breaks may be accentuated by shadows (figs. 88 and 97).

SIZE

The quantitative element of size, as it relates to surface or volume dimensions of an object, has been little used in recognition of geologic features from aerial photographs, although relative size has been useful as an interpretation aid. Size as an interpretation element is being used increasingly with the adoption of photogrammetry as a fundamental part of photogeology; it is most appropriately considered in relation to interpretations based on thickness of strata, amount of offset along faults, or other finite measurements (see p. 56-63). Geologically significant measurements may be directly related to topographic expression; that is, measurements between topographic positions may yield direct information such as stratigraphic thickness. But generally other influencing factors, such as dip of beds or other structural elements, must be considered just as in field measurement (see p. 56-58). If the thickness of a formation is known, it may aid in location of formation contacts on aerial photographs, because measurements may be made from known points that would permit the positioning of the obscured contacts (fig.

39); or it may aid in correlation of beds across fault zones. Determining the range of thicknesses over a broad area may be essential to understanding the regional geology of that area (see p. 59-60).

Studies in quantitative geomorphology suggest that size, in terms of finite measurements, may be an extremely important parameter of geologic interpretation of aerial photographs. Measurement of geologic data can be expected to become an even more important part of photogeology in the future as techniques of quantifying geologic information become more widely used.

COMBINATIONS OF RECOGNITION ELEMENTS

The usefulness of recognition elements, of course, is enhanced where they may be used in combination. Indeed, photographic tone, useful alone as a recognition factor under some conditions, is a fundamental photographic characteristic without which there could be no recognition elements at all on black-and-white photographs. As mutually supporting recognition elements an association of photographic tone, topographic expression, and texture may permit the interpretation of bedding, even in areas of sparse or no outcrops (fig. 40). Faults are commonly expressed as straight or gently curved lines; they may be further identified by an abrupt photographic tone change on opposite sides of these lines as well as by a pronounced offset of recognizable rock types (fig. 83). Surficial materials are commonly identified on the combined basis of stream patterns, shapes of gully cross sections, texture, and photographic tone as well as by their relation to associated features (see p. 34-37).

VERTICAL EXAGGERATION

In addition to those recognition elements that are based on factors, such as film and filter used and processing, that directly affect the photographic image, certain other factors are important in interpretation. Especially significant is vertical exaggeration—the exaggeration of vertical distances with respect to horizontal distances—which is characteristic of almost all stereoscopic models; this exaggeration makes slopes appear steeper than they are and objects seem taller than they are. Vertical exaggeration is generally present not only in viewing stereoscopic models formed from paper prints but also in viewing projected stereoscopic models formed from glass-plate diapositives in double-projection instruments.

An understanding of vertical exaggeration is fundamental in the study of stereoscopic models, not only because of the exaggerated heights and the somewhat unnatural view that results, but because in many geologic problems the interpreter relies on visual dip

estimations rather than on any measuring devices (see p. 64). The amount of exaggeration of a dip angle in a stereoscopic model is fundamentally related to the tangent of the dip angle; that is, in a stereoscopic model exaggerated 3 times, for example, any true dip angle would be exaggerated to an angle whose tangent function was equal to 3 times the tangent of true dip. Exaggeration of low dips is generally an aid in structural interpretation and in detecting tilt from aerial photographs.

Minor topographic differences, which may reflect underlying geologic structure, are also exaggerated and in turn easily recognized (figs. 40, 88, and 97). The exaggeration of relief in a stereoscopic model of 1:20,000-scale photographs taken with a 6-inch-focal-length lens commonly permits an interpreter to distinguish differences in altitude as small as 1 foot. As a consequence vertical exaggeration then is most important where small but significant differences in altitude may be present in the stereoscopic model.

Vertical exaggeration results from the wide spacing of the camera positions at the time of exposure, as contrasted to the spacing of the human eyes with respect to normal viewing arrangement in examining stereoscopic models. Vertical exaggeration in normal viewing arrangement is fundamentally related to base-height ratio, which is the ratio of the air base distance to the flying height (see fig. 1). As this ratio increases, vertical exaggeration increases. Thus the greater the distance between camera stations (equivalent to air base distance), flying height remaining constant, the greater is the vertical exaggeration. The resulting photographs will have an increasingly smaller overlap area and consequently a lesser area within the stereoscopic model. It should be noted, however, that in normal photographing procedure when flying height is increased for any given focal-length lens, the air base distance is also increased so that a relatively constant base-height ratio is maintained. Under these conditions vertical exaggeration is not affected by flying height. When the base-height ratio is increased through the use of short-focal-length lenses, vertical exaggeration will also increase, the photographs taken with the shorter focal-length lens showing the greater exaggeration. Effective vertical exaggeration may also be increased by moving the two photographs farther apart at the time of viewing, or by increasing the viewing distance.

SCALE OF PHOTOGRAPHS

Small-scale photographs may be advantageous for interpreting some geologic terrains, particularly where reconnaissance information is desired. Small-scale pho-

tographs are normally taken at relatively high altitudes and have scales of 1:60,000 or smaller; their usefulness results chiefly from showing a large area in a single view (approximately 80 square miles on a single photograph having a scale of 1:60,000), which may reveal overall relations, as in geologic structures, drainage patterns, or other features, that could not be readily seen otherwise (figs. 48 and 55). Photomosaics commonly serve this same purpose (fig. 96). The association of features over a large area provided by the small scale is the significant factor to be considered. However, the reduction in image size due to high flying heights or short-focal-length lenses may be detrimental to the identification of some features, and hence make such photographs of little use for some interpretation problems. For example, details of jointing may be entirely lost on small-scale photographs. Also, use of small-scale photographs obtained by using extremely short-focal-length lenses, that is, 2 inches or shorter, may be undesirable, especially in areas of moderate to high relief, because many topographically low areas will be masked from view. Nevertheless, small-scale photographs have definite advantages in qualitative interpretation (Hemphill, 1958b) and may be especially useful if employed in conjunction with large-scale photographs or with instruments that enlarge the photography scale (see p. 47). Where quantitative study is involved, small-scale photographs are advantageous in that less control is needed within a given area than with large-scale photographs; but this advantage may be offset by the decrease in the reliability of measurements (see p. 72-74).

PHOTOGEOLOGY IN GEOLOGIC MAPPING

In geologic mapping maximum use of aerial photographs is attained by closely integrating field and photogeologic studies. It generally is desirable to precede the field phase of geologic study by a study of aerial photographs, which should include the compilation of a preliminary map on which all interpretations, however reliable or questionable, have been noted. Such a preliminary photogeologic study affords several advantages: it may point out areas that must be mapped primarily by field methods; it may eliminate or reduce extensive field surveys in certain areas; it may direct attention to anomalous areas where detailed field study is particularly warranted; and it commonly provides a basis for organizing the geologic plan of field study. In addition, attention is directed to those areas where field study will most likely result in establishing criteria that will permit a refinement of further photogeologic mapping. Also, a preliminary study of photographs gives a geographic familiarity of the area

that would be useful in choosing camp sites, routes of traverse, and optimum locations of instrument survey stations.

Continuing use of aerial photographs during the field phase of geologic study permits a firsthand correlation of geologic features and photographic images, which corroborates or refutes preliminary interpretations and provides information for subsequent detailed photointerpretive study. Refinements in interpretation may be made in the field or in a followup photogeologic study.

The delineation of rock types and structures from aerial photographs may involve mere observation; or more commonly interpretation is involved. In some areas it is possible only to map similar photographic units, as no diagnostic or suggestive criteria as to rock type may be present. Such areas are usually poorly exposed because of heavy vegetation or surficial debris; relief may be very low. But in other areas, where wide expanses of rock crop out, specific formations or rock types may be easily delimited on the photographs; thus much of the routine work of mapping geologic contacts, as well as determining structural measurements, can be accomplished readily by photogeologic methods. Where geologic structures are small and complex, aerial photographs may provide only limited information as contrasted to areas where geologic structures are large and simple. Depending chiefly on factors related to geologic environment, climate, and erosional cycle, the extent to which photogeologic methods can be applied thus may vary widely.

KINDS AND AMOUNTS OF INFORMATION

Geologic information that can be interpreted from aerial photographs may be grouped broadly into two categories: lithologic and structural. In general or reconnaissance mapping the geologist is interested largely in determining the distribution of rock units, including surficial deposits, and in delineating geologic structures. Special studies may require a more rigorous application of photogeologic procedures, which includes quantitative as well as qualitative study of the stereoscopic models. But regardless of the objective of a particular study, the kinds and amounts of geologic information available from aerial photographs will depend primarily on the type of terrain—whether igneous, metamorphic, or sedimentary—the climatic environment, and stage of the geomorphic cycle.

It is generally believed that sedimentary rock areas will yield more information from aerial photographs than igneous rock areas, and that regions underlain by metamorphic rocks will reveal the least information.

Putnam stated (1947, p. 560, 562) that “* * * geologic features * * * tend to be more recognizable where strong differences exist in the erosional resistance of adjacent rocks. Thus, sedimentary rocks, as sandstone, shale, and limestone, are likely to be more apparent than relatively homogeneous rocks like granite, especially if the sedimentary rocks have a moderate dip.” Bentor (1952, p. 162), based on his work in Israel, was of the opinion that “As a whole, air-photographs are much less useful in regions of crystalline rocks than in those composed of sedimentary formations.” With regard to igneous and metamorphic terrains, which are generally believed to be more difficult to interpret than sedimentary terrains, Melton (1956, p. 57) concluded that “Discovery of hitherto unknown or abnormal structures and [mineral] deposits, rather than detailed mapping, will probably be the most rewarding use of aerial photographs * * *.”

Except for high mountainous areas where vegetative growth is restricted by altitude, arid and semiarid regions generally will have the largest areas of rock outcrop, and tropical regions the least; hence the arid and semiarid regions may be expected to yield the greatest amount of geologic information from aerial photographs. In addition to relatively wide areas of rock exposure, the arid and semiarid regions may be expected to show a greater number of significant plant-rock associations than other climatic areas, because weathered material in the arid and semiarid regions is not excessively leached and a close relation of soil to parent formation therefore persists. Where this close association of parent rock and residual soils exists the distribution of different vegetation, reflecting the effect of bedrock on the composition of the soils, may facilitate the mapping of different rock types (see Levings, 1944, p. 27–30). In areas of much precipitation, under temperate or tropical climatic conditions, soils tends to be leached of salts, and there is a further tendency for soils from different parent formations to become more similar at maturity (Murray, 1955, p. 104). Murray stated (1955, p. 104) that under tropical conditions where rainfall is abundant, the ratios of potassium, sodium, and calcium to aluminum, which are widely different in silicic and mafic rocks, become smaller on weathering and are nearly equal in mature soils. Thus differences in vegetation as related to specific formations might be less well developed in tropical areas, except for those plant associations that may depend primarily on physical characteristics of the soil rather than chemical. Grantham (1953, p. 329) noted that in semiarid areas of Africa the soils reflect geology through vegetation differences more strongly than in wet temperate areas.

Sedimentary terrains yield a greater amount of lithologic and structural information than igneous and metamorphic areas because of the generally nonhomogeneous nature of sedimentary terrain, which results in marked differential erosion characteristics that stand out on aerial photographs. Sedimentary rocks of strongly differing physical characteristics commonly crop out within short distances whereas plutonic rocks, particularly, are likely to be relatively homogeneous over wide areas. Locally, diagnostic landforms, such as volcanic cones, may be important in study of igneous terrains, especially where extrusive rocks prevail. Metamorphic terrains, on the other hand, may reveal the least amount of information from aerial photographs because of the very nature of the metamorphic processes, which tend to destroy the erosional and landform characteristics of sedimentary and igneous rocks from which the metamorphic rocks are derived.

In any area where vegetative cover is dense and where surficial debris is widespread, aerial photographs generally can be expected to yield more structural information than lithologic information. The amount of structural information in turn generally will be greater, for any one type of terrain and climatic environment, during the mature stage of the geomorphic cycle, at which time streams show their greatest adjustment to and reflection of structure, and at which time a greater third dimension of the terrain is visible for study in the stereoscopic model. Where the lithologic character of rocks is interpreted on geomorphic or landform expression, maturely dissected areas may reveal the greatest amount of information.

Although the extent to which photogeologic procedures contribute to the geologic mapping of an area depends on the climatic and geologic environment, as well as the stage of the erosional cycle, some generalizations may be stated with regard to differentiating and interpreting sedimentary, igneous, and metamorphic terrains. These generalizations are grouped into two categories: lithologic character of rocks and geologic structure.

LITHOLOGIC CHARACTER OF ROCKS SEDIMENTARY ROCKS

Consolidated.—The presence of bedding in most sedimentary rocks is fundamental to their interpretation from aerial photographs. Because of differential resistance to erosion of sedimentary beds the typical banded patterns of these rocks are seen on aerial photographs. This is a result of what Rich (1951, p. 189) termed the "etching concept" wherein more resistant beds are brought into relief and less resistant beds

lowered as a result of weathering and removal of materials largely by sheet wash and creep (figs. 87, 91, and 97). Back slopes of steeply dipping beds, especially, may contrast strongly because they commonly expose to erosion within a given area a wider variety of lithologic types than dip slopes of gently dipping beds. Although topographic expression is thus important in recognition of bedding, banding due to vegetation or soil differences, expressed by photographic tone may likewise delineate beds, in absence of topographic expression or in combination with it (figs. 40 and 81). Bedding is especially prominent in the mature stage of the geomorphic cycle, particularly in terrain underlain by interbedded hard and soft sedimentary rocks that are tilted. However, bedding may be masked by the massive character of some sedimentary rocks, such as certain sandstones, in which case the sedimentary rocks may appear to be homogeneous and similar to some metamorphic rocks or intrusive igneous rocks as seen on aerial photographs (contrast figs. 71 and 92). A notable exception is massive limestone in which sinkholes have developed (fig. 68).

As seen on aerial photographs shales and similar fine-grained sedimentary rocks tend to have relatively dark photographic tones, a fine-textured drainage, and relatively closely and regularly spaced joints (figs. 49, 62, 63, and 91). Coarse-grained clastic rocks, in contrast, tend to have relatively light photographic tones, a coarse-textured drainage, and relatively widely and regularly spaced joints (figs. 42, 91, and 92). These generalizations are probably most applicable to marine sedimentary rocks. However, some fine-grained clastic rocks may be light toned and some coarse-grained sedimentary rocks, such as the continental red beds, may be dark colored rather than light colored and be expressed as relatively dark photographic tones on aerial photographs. Drainage density in a given climatic area is related primarily to resistance of a rock to erosion; drainage density increases with decrease of resistance to erosion. Resistance to erosion in turn is fundamentally related to permeability; generally resistance to erosion is less in rocks of low permeability. Hence, fine-grained clastic rocks commonly have a fine-textured drainage (fig. 79).

Physico-chemical precipitates are in many places closely associated with fine-grained clastic sedimentary rocks; where these rocks are interbedded the drainage texture and joint pattern both may be fine, as with fine-grained clastic rocks alone, but photographic tone of physico-chemical precipitates may commonly be relatively light, as with some fresh-water limestone, rather than dark, despite the fine grain size.

Although fine-textured drainage commonly characterizes nonresistant fine-grained sedimentary rocks and coarse-textured drainage suggests resistant coarse-grained sedimentary rocks, drainage is probably more significant as an indicator of structure than it is of lithology. Drainage characteristics may suggest broad rock groupings, but no one drainage pattern is diagnostic of sedimentary rocks, although annular and trellis drainage generally suggest sedimentary rocks or close metamorphic equivalents. The association of specific drainage characteristics with rocks of certain lithologic or physical characteristics presents an interesting field of study; quantitative study of stream data measureable from aerial photographs, such as drainage density, may indicate certain drainage-lithology relations.

The type of vegetation may be useful in differentiating specific rock types (see figs. 43 and 61). Hemming (1937) noted that striking vegetation differences were exhibited by limestone and quartzite in northern Rhodesia where the trees *Acacia* and *Albizzia* grew on limestone and *Brachystegia* and *Isoberlinia* grew on quartzite.

Unconsolidated.—Most surficial deposits—the unconsolidated sedimentary rocks—are readily distinguished on aerial photographs from consolidated rock types, although thin veneers of surficial material may be difficult to identify. Many recognition criteria are used in identifying and interpreting surficial deposits from aerial photographs, but the most significant criterion is probably landform. Landform is significant because many surficial deposits, particularly those useful to the engineering geologist, are transported materials that have diagnostic topographic form. The importance of landform is seen in the identification of sand dunes, eskers, kames, alluvial fans, river terraces, and similar constructional geologic features (figs. 52, 55, 56, 58, and 104). On the other hand extensive deposits of surficial debris, such as the drift plains of north-central United States, may show little or no diagnostic landform, but their general makeup may be inferred from drainage characteristics, photographic tone, analysis of slope, and related criteria (fig. 107). These criteria are discussed more fully under uses of aerial photographs in engineering geology studies (p. 33–37).

IGNEOUS ROCKS

Extrusive rocks.—Extrusive igneous rocks commonly have diagnostic landforms (figs. 41, 60, and 76) in contrast to the intrusive igneous rocks, which are revealed on aerial photographs primarily by other recognition features such as drainage, texture, massive

character of the rock, and crosscutting association with country rocks.

In addition to landform certain other criteria may be useful in identifying extrusive rocks, if the terrain is relatively undeformed. The structural relation of flows to associated rocks, for example, may be diagnostic in little-deformed areas, but where flows have been strongly tilted, folded, or otherwise disturbed, recognition and interpretation from aerial photographs may be extremely difficult or impossible. Only those relatively undeformed flows, mainly of Tertiary age and younger, are readily identified from aerial photographs without some knowledge from ground surveys. The ground plan of flows showing lobate patterns of vegetation and topography, especially at the terminations of suspected flows, is commonly diagnostic (figs. 76, 85, and 113), and association with volcanic cones makes misinterpretation difficult (figs. 41, 60, and 76). Locally flow channels may be visible. The surface of a flow may be rather hummocky and irregular, in contrast to surfaces of sedimentary strata, and where several flows have piled up, present topography may show several terracelike forms with irregular surfaces. The unconformable contact between flows and underlying rocks may aid in recognizing extrusive rocks (fig. 87), and where flows cascade down over older topography their identity is obvious (fig. 60). The basaltic or mafic flows may show dark photographic tones on conventional photographs, particularly in well-exposed areas, whereas rhyolitic or silicic flows may have light photographic tones. Locally distinctive patterns are present on mafic flows (fig. 53), and in some areas erosional characteristics permit differentiation of flows and associated rocks (fig. 69).

Where flows have been extruded over deformed igneous and metamorphic terrains, a low-dipping surface associated with lobate patterns of vegetation and topography is suggestive of extrusive rocks, and in some areas faults in the underlying rocks are seen to terminate abruptly at the edge of a lava flow (fig. 85).

Intrusive rocks.—Intrusive igneous rocks have a wide variety of structural relations to surrounding rocks that commonly aid in their identification from aerial photographs. Dikes may be revealed on aerial photographs as rectilinear or curved ridges that stand up because of greater resistance to erosion than surrounding rocks (figs. 81, 82, 87 and 90); they may also contrast in photographic tone with the surrounding rocks either because of the difference in rock types (fig. 90), or because of distinctive vegetation that covers dikes in some areas (Mogg, 1930, p. 662 and 668, pl. 5). Dikes may follow fractures in other igneous rocks and contrast in photographic tone with the host

rock. Where dikes are less resistant than the country rock, they may be expressed as rectilinear depressions that appear similar to fault expressions.

Because sills occur parallel to bedding in sedimentary rocks, they may be difficult to interpret as igneous from aerial photographs, even though strong tonal contrasts of the sills and sedimentary rocks are present. Mogg (1930, p. 656) pointed out that the diabases of Pretoria, South Africa, although relatively hard rocks, weather easily to deep soils that support distinctive deep-rooted vegetation, but the vegetation type differs from area to area. The tree *Kirkia wilmsii* grows conspicuously and exclusively on diabase sheets in the sedimentary rocks of the Pyramid Hills area of Pretoria (Mogg, 1930, p. 658), but in the Magaliesberg area *Acacia caffra* characteristically marks the diabase (Mogg, 1930, p. 662). Vegetation thus may be important locally as an indicator of rock types, but commonly it must be interpreted with caution because the same rock type may carry a different flora in different areas.

Igneous plugs, laccoliths, stocks, and batholiths, by nature of their mode of origin, commonly tilt the sedimentary rocks which they intrude, and in areas where plutonic rocks are exposed the pattern of dips in surrounding rocks may support other criteria suggestive of igneous rocks. Domal areas due to intrusion may also be reflected in radial drainage patterns (fig. 48), just as are certain folds in sedimentary rocks. But if areas of plutonic rocks are large, the characteristic homogeneous nature of such rocks may result in a dendritic drainage pattern, unless drainage is controlled by a fracture system (figs. 51, 70, 71, and 86). Because of the generally homogeneous nature of plutonic rocks as contrasted to sedimentary rocks they will have a massive appearance on aerial photographs, and banding typical of sedimentary and some metamorphic rocks will generally be lacking (figs. 59, 70, and 71). Also because of the homogeneous character of many igneous bodies, elements essential to plant growth may be distributed more or less uniformly throughout the mass (Murray, 1955, p. 103) and significant differences in vegetation can be expected to be absent from any one plutonic rock mass (fig. 70), except for those differences controlled by altitude or by structural conditions, such as faults that may trap an abundance of moisture (fig. 71).

In addition, topographic and erosional characteristics may aid in the interpretation of some igneous terrains. Granite at low altitudes in some tropical areas is expressed in hummocky, rounded topography on which a uniform type of vegetation is present; dendritic drainage may characterize this terrain.

Similar rounded topography may also be present at high altitudes, but where glaciers have been active all rocks may stand out in sharply angular topography. Regardless of surface expression, however, a crisscross pattern of joints, nearly always present in igneous rocks, commonly can be seen not only in the well-exposed areas (see figs. 70, 71, 100, and 103) but also in many vegetation-covered areas (fig. 72). Topographic expression of most plutonic rocks, as with other rock types, is dependent in large part on climate and stage of the erosional cycle, although within an area underlain by different igneous rock types difference in resistance to erosion may be significant and specific rocks may stand topographically high (see fig. 82). The homogeneous character of many intrusive rocks and characteristic jointing, on the other hand, are related primarily to the rock type and its mode of occurrence, and are independent of climate and erosional cycle.

METAMORPHIC ROCKS

The identification and interpretation of metamorphic rocks from aerial photographs is commonly difficult because large-scale distinguishing characteristics are generally lacking. Bedding, so necessary to structural interpretation, may be difficult or impossible to recognize because of physical changes brought about by metamorphism, including the superposition of metamorphic structures of small scale. Indeed, many structural trends that can be interpreted from aerial photographs represent foliation rather than bedding (figs. 73 and 74). Where exposures are good, differences in photographic tone offer the best clue to recognition of bedding, especially where the metamorphic rocks are derived from thin-bedded sedimentary rocks of contrasting lithologic makeup (fig. 103). Thick formations of quartzite and marble might readily retain the photographic characteristics of the original sedimentary beds, however, because the metamorphic changes of induration of sandstone and recrystallization of limestone would likely have little effect on the gross physical appearance of these rock types as seen on aerial photographs. It is possible, however, that talus from quartzite ledges might take the form of large blocks in contrast to smaller chunks of rubble at the base of sandstone cliffs. The preference of vegetation for one rock type such as limestone, as a result of its chemical makeup, might well persist, even if the formation were metamorphosed to marble; but vegetation that might show a preference for sandstone because of its physical makeup, especially its high porosity, might well be lacking on its metamorphic equivalent, quartzite.

Strong parallel alignments of ridges and intervening low areas may be due to regional cleavage, foliation,

or fold axes, and thus the "topographic grain" of an area may suggest underlying metamorphic rocks (figs. 73, 76, 100, and 102), but in glaciated areas this evidence must be used with caution (fig. 67). In an area where a pronounced regional trend, or "topographic grain," is shown on the aerial photographs, the likelihood that metamorphic rocks are present is supported by the occurrence of widely spaced lineations at right angles to the regional trend. These lineations commonly represent regional cross joints and may be reflected in abrupt deflections of drainage along conspicuous straight stream segments of major streams (fig. 74) or in the development of tributary streams along these joints (figs. 73-75). Where bedrock is well exposed the profuse fractures in certain metamorphic rocks may be visible (figs. 46 and 99). Cady (1945) pointed out that in some areas in central Alaska talus slopes are developed much more extensively where the peaks are of metamorphic rocks rather than of granitic rocks; this distinguishes these two rock types locally (fig. 103).

STRUCTURE

FLAT-LYING BEDS

Flat-lying or nearly horizontal beds are most easily recognized where different sedimentary rock types exhibit contrasting photographic tones expressed as bands that extend along the topographic contour (figs. 77 and 78). Where both resistant and nonresistant rocks are present slope characteristics commonly are suggestive of horizontal strata—the resistant rocks have steep slopes or vertical cliffs, and the nonresistant rocks have a lesser angle of slope; the significant changes in slope between two beds extend generally along the topographic contour (figs. 77 and 78). Photographic tone and slope characteristics are associated in many places as mutually supporting evidence of flat-lying beds.

Because of the uniform resistance of one rock type to erosion, particularly in a horizontal direction, the drainage on flat-lying beds is generally dendritic unless controlled by joints or faults (figs. 42, 61, and 77). However, dendritic drainage alone, although suggestive, is not necessarily diagnostic of flat-lying sedimentary rocks; other rock types, such as granite, also may be uniformly resistant to erosion and may also exhibit dendritic drainage.

DIPPING BEDS

Numerous expressions of dip of sedimentary beds may be seen on aerial photographs. Dip direction is readily apparent where topographic surfaces coincide with bedding surfaces (figs. 87, 90, 92). Even in heavily vegetated areas the direction of dip commonly

stands out as a result of the overall view afforded by the aerial photograph, which shows the tree crowns to fall in a dipping plane (fig. 89). In those areas where dips are very low, the aerial photographs are advantageous, if the beds are clearly expressed, because vertical exaggeration, which is present in most stereoscopic models, permits low dips to be readily interpreted (see fig. 91 and p. 64). The degree of dip may be estimated from the stereoscopic model by experienced photointerpreters or it may be measured photogrammetrically.

Where bedding is expressed by bands of differing photographic tone or by topographic breaks in slope due to resistance of beds, the rule of V's may be applied to determine the direction of dip; that is, where the trace of a bed intersects a stream valley a V in the outcrop pattern will point in the direction of dip (figs. 80, 81, and 98) unless the direction of dip and direction of streamflow are the same and the stream has a gradient greater than the amount of dip (fig. 59).

In many areas, particularly those of low relief, where beds are obscured by surficial materials or vegetation the direction of dip may be inferred from drainage characteristics. Where dips are gentle the relatively long tributary streams commonly flow down the dip slopes (Lattman, 1954, p. 361-365), whereas short tributary streams will characterize back slopes (figs. 5, 7, and 74). It is interesting to note that the relation of short and long tributary streams may be reversed where dips are steep, that is, about 45° or more (fig. 6). Other photorecognition criteria, such as distribution of photographic tones, should be sought to indicate whether dips are gentle or steep; or scattered field observations may provide sufficient information for making an analysis of dip direction based on stream characteristics. In such an analysis it may be desirable to trace all streams, however small, on a separate overlay (fig. 7). This is best done from the stereoscopic model. Exact positioning of tributaries is not essential to this technique of determining dip direction, but lengths of tributaries must be sketched carefully as the length relations of updip to downdip tributaries is significant. Viewing the stereoscopic model pseudoscopically (fig. 95) may be helpful in delineating the drainage.

FOLDS

Folds are commonly expressed as obvious features on aerial photographs especially where a fold is shown in its entirety within a single view and an orderly structural arrangement of beds is discernible (fig. 90) or where erosion has exposed a cross section of the

FIGURE 5.—Sketch showing long tributary streams on updip side of strike valley in area of low dips.

FIGURE 6.—Sketch showing long tributary streams on downdip side of strike valley in area of steep dips.

structure (fig. 91). Drainage characteristics may also aid in recognizing and delimiting the fold. Wengerd (1947, p. 596) noted that in parts of northern Alaska streams flowing in synclinal valleys were sluggish and meandering, and had low banks and swampy border areas with meandering tributaries; in contrast, streams flowing in anticlinal valleys were steep walled and less meandering. Wengerd also noted that dip slopes and back slopes in some areas commonly exhibited different drainage densities (fig. 79).

Where folds are plunging, major streams commonly curve around the nose of the fold; the convex side of the curve indicates the direction of plunge of anticlinal folds (figs. 81, 89, and 90). However, in areas where relief is low or bedrock is obscured by vegetation or surficial materials, drainage patterns or drainage anomalies may be the primary expression of folds (see figs. 9, 94, and 96; and p. 26-27). Drainage patterns or anomalies generally are best seen on small-scale photographs or mosaics where segments of streams combine to form significant patterns when observed in a single view (fig. 96). The significance of drainage characteristics may not be immediately apparent when large-scale photographs are viewed.

FAULTS

One of the advantages in study of aerial photographs is that of delineating high-angle faults or suspected faults. This advantage is a direct result of the aerial view, which allows a large area and the gross features within it to be seen at one time. For example, many alinements that are inconspicuous on the ground are readily seen on aerial photographs (figs. 74 and 83). Although many alinements are conspicuous because of their independence of stream valleys or ridges and uplands which they cross (see Barton, 1933, p. 1198), alinements of stream segments and small drainage courses are probably the most common indicators of faults. Most high-angle faults are expressed on photographs as straight or gently curving lines, and this characteristic is probably the most important clue that a fault may exist. All linear features should be examined with care even though other criteria are needed to prove the existence of faults.

Lines indicative of faults may be expressed as alinements of vegetation, straight segments of stream courses, and waterfalls across streams; alinements of lakes, ponds, and springs; conspicuous changes in photographic tone or drainage and erosional texture on opposite sides of a linear feature, or tone change along a linear feature because of vegetation which may appear darker; alinements of topography, including saddles, knobs, or straight scarps; rectilinear depres-

sions; or any combination of these. Faults may also be expressed by horizontal or vertical offsets of beds or recognizable rock units (figs. 50, 60, 62, 74, 79, 80, 82-84, 86, 98, 99, 101, and 114). Where bedrock is well exposed the actual physical break may be seen. In some places a lineament, or broad linear depression, may be conspicuous but not distinct. Where such areas of possible faults occur, beds on one side of the general lineament should be examined for change of dip and strike as well as abnormal stratigraphic position with respect to beds on the other side (see fig. 80). Commonly in sedimentary terrain, offsets on opposite sides of a linear feature are easily detected, owing to the vertical exaggeration which is inherent in most stereoscopic models and which generally assists in the identification of correlative beds (figs. 83 and 84).

Suspected faults should be examined carefully because other features may be represented, at least in part, on aerial photographs in the same manner as faults, particularly if a single photograph is being viewed. In some areas jointing in one direction within a formation may be prominent and where an apparent offset is present owing to the occurrence of an erosion scarp along a joint plane, the scarp line may be misinterpreted as a fault trace. Where channels have been cut in sedimentary formations, and a rock type of different lithologic character now occupies the channels, a distinct lineation between the channel filling and the original sedimentary rock, now truncated, may suggest a fault trace. A line between two distinct types of vegetation, although possibly reflecting the presence of a fault, may well be due to differences in underlying rock types in normal sequence, or to the moisture content of the soil, or even to manmade features. In some areas the simple erosion of dipping strata may result in an alinement of topographically high points that suggests a fault. Or vegetation and drainage alinements may be present along easily eroded dikes. The need for caution in interpreting faults from aerial photographs is thus dictated by the very presence of numerous other geologic features that are expressed photographically in a similar manner.

Low-angle faults are more difficult to interpret from aerial photographs than high-angle faults. Discordance of structures within different rock types combined with strongly curving or irregular traces of the fault contact of the rocks involved offer the best clue to the presence of low-angle faults. Angular unconformities may show similar photographic expression.

In a study of azimuth, frequency, and length measurements, Gross (1951) demonstrated that in some covered areas of the Canadian Shield certain lineations very likely represent faults. The study involved the

FIGURE 7.—Drainage map of area shown in figure 74 and vicinity. (Strike and dip positions based on analysis of stream-length relations.)

The separate drainage tracing allows a study of drainage characteristics divorced from the abundant imagery of the photograph. Patterns and tributary stream-length relations, for example, are readily observed on the separate tracing. Relative lengths of tributary streams at many places might easily be overlooked in the stereoscopic model. However, a study of the plani-

metric disposition of streams must be considered a supplement to a study of the stereoscopic model in which significant features in the third dimension, such as elongate hills or other features that may represent structure, are seen.

construction of histograms in which the length and frequency of topographic lineations as seen on aerial photographs were plotted against geographic orientation within 10° segments of the compass. Similarly, histograms were plotted from a sampling of field data of strike of strata, schistosity, dikes, glacial striae, faults, and other features considered to have a bearing on the configuration of the topography. One peak on the histograms compiled from aerial photographs was found to represent a direction of prominent faulting.

JOINTS

Joints, like faults, are most commonly expressed on aerial photographs as linear features. In flat-lying or gently folded sedimentary rocks, most joints are steeply dipping or vertical, evenly or regularly spaced, and commonly consist of two prominent sets that are expressed on aerial photographs as lines intersecting approximately at right angles, which gives a blocky appearance to the topography (fig. 42); however, joints may be well developed in only one direction, which gives a strong linearity to the fracture plan (fig. 92). In fine-grained clastic rocks the joints are generally more closely spaced than in coarse clastic rocks. Joints may become widened through weathering and erosion processes and appear as particularly conspicuous linear features; the similarity of these joints to faults is superficially striking, especially where well-developed regional cross joints have formed in metamorphic rocks and other criteria of faulting are lacking. Identification of many joints is enhanced by the presence of vegetation along them, due perhaps to greater moisture along these lines. Lattman and Olive (1955, p. 2087) described the use of solution-widened joints in Texas as a guide to indicate steepening of dip and to locate changes in dip direction. Joints more nearly parallel to the dip direction were widened by solution of meteoric water. Rubble, soil, and water trapped in these joints gave rise to dense vegetation expressed on aerial photographs as conspicuous, even-spaced parallel lines. A good clue to the identification of joints in relatively undisturbed sedimentary rocks is the general abundance of short lineations on a photograph, and a more or less uniform trend of these lineations within a given area of a few square miles extent.

Lattman and Nickelsen (1958) described azimuth-frequency measurements from aerial photographs in a study of fracture traces in western Pennsylvania. The fracture traces are expressions of natural linear features that consist of topographic, vegetation, or soil

alinements exposed continuously for less than 1 mile. The term "fracture trace" is used by Lattman (1958, p. 569) to differentiate these alinements from natural linear features exposed continuously for at least 1 mile or more, called "lineaments." A histogram of frequency and orientation of the fracture traces showed maximums closely corresponding to those of prevailing directions of joints as seen in the field, with the exception of one fracture-trace maximum which had no counterpart in exposed rocks of the area (Lattman and Nickelsen, 1958). This one maximum of frequency and orientation of traces, however, was found to correspond with joints in underlying coal beds; the joints apparently were reflected through an overlying thickness of shale and sandstone to be expressed at the surface in a manner discernible on aerial photographs but not in routine field-mapping procedure. The close correspondence of fracture traces and joint directions in the test area suggest that aerial photographs may be used to extend mapping of joints into nearby areas of no outcrop.

Joints in igneous rocks are likely to be seen readily on aerial photographs (figs. 70, 71, 100, and 103). Commonly three and sometimes four prominent joint sets are developed. Where these joints are primary joints, dips may be low, moderate, or steep, depending on the orientation of flow structures within the igneous mass; this contrasts with the generally steep dipping joints of little-disturbed sedimentary rocks. Because of the wide range of dips of joints in igneous rocks, and because at least three joint sets are almost always developed, the surface traces of these joints, shown as lineations on aerial photographs, intersect at widely varying angles. The resulting crisscross pattern is distinctive of intrusive rocks in many areas. Joints in igneous rocks also may be irregularly spaced in contrast to those in sedimentary rocks.

Joints in metamorphic rocks may not be as conspicuous on photographs as joints in sedimentary or igneous rocks. Joints previously formed in igneous or sedimentary rocks may be destroyed by metamorphic processes and much of the energy of metamorphism spent in development of schistosity, fracture cleavage, or other small-scale metamorphic structures, rather than conspicuous joints. This is particularly true of metamorphic rocks formed from fine-grained clastic rocks, which comprise more than 50 percent of the sedimentary rock group. Where metamorphic rocks are recognizable by strong lineations that represent fold axes or trend of foliation, widely spaced regional cross joints perpendicular to the fold-axes direction may be prominent; streams developed along the cross joints accentuate these structures (figs. 8, 73, and 74).

CLEAVAGE AND FOLIATION

Cleavage or foliation, which is almost universally present in metamorphic rocks, especially in those that were originally shale or other thin-bedded clastic rocks, is difficult to differentiate on most aerial photographs. The "grain" of metamorphic terrain as expressed on aerial photographs by stream and vegetation patterns, as well as by parallel ridges and gullies, however, may well reflect pronounced cleavage or foliation (figs. 76 and 100). Turner (1952) pointed out that prominent topographic alinements in the schists of central Otago, New Zealand, are clearly expressed on aerial photographs. These alinements, generally parallel to the trend of *b* lineations, are believed to have resulted from differential weathering controlled by cleavage, foliation, and other elements of the schist fabric.

UNCONFORMITIES

Unconformities are generally difficult to interpret from aerial photographs. An angular unconformity may be inferred from the discordance of bedding, either in strike, dip, or both, at a contact line that has an irregular trace across a wide area. But discordance alone does not prove the presence of a stratigraphic unconformity since a discordance of bedding may be due to faulting, or locally to crossbedding. The areal distribution of rocks or structures as seen on small-scale photographs or mosaics, or after plotting geologic data over a large area, may also suggest the presence of an unconformity. On a local scale, the separation of unconsolidated, nearly horizontal, river gravel from the truncated, underlying strata is a good example of an unconformity (fig. 88). Pediment gravel that overlies truncated bedrock (fig. 45), or channel-fill deposits that truncate the underlying bedrock (fig. 44), may be clearly expressed on aerial photographs.

INTERPRETATION OF AERIAL PHOTOGRAPHS IN PETROLEUM GEOLOGY

Aerial photographs have been widely used by geologists of the petroleum industry particularly in the mapping of many large-scale geologic structures, which are readily recognized on aerial photographs because of direct surface expressions of dipping beds. The use of photogeologic techniques in the search for structures that may contain oil is continuously increasing. However, as the obvious and well-exposed structures in many areas have long been discovered, considerable attention is now being given to indirect, or geomorphic evidence of subsurface structures. In addition, photogrammetric methods for making measurements needed to compile structure contours and to

FIGURE 8.—Drainage map of area shown on left half of figure 73.

The regional cross-joint trend, expressed by the main streams on figure 73, is strongly brought out on the drainage map. Note tributary streams flowing at right angles to the main streams. Stream trends are obscured com-

monly by the abundant imagery of the photograph and it may be desirable to compile separate drainage maps when stream characteristics are used to interpret lithologic or structural features of an area.

determine strike, dip, stratigraphic thickness, and closure are being used increasingly.

The indirect evidence yielded by photointerpretive studies is based on the premise that subsurface structures may be reflected in surface expressions of various kinds, such as stream or vegetation patterns or anomalies. Indirect evidence is particularly useful in the interpretation of areas of few or no outcrops, such as areas of low relief, or areas of dense vegetation. Commonly in such areas, the evidence points not directly to a structure, but to an anomaly, such as a variation in drainage characteristics from the norm established for a local region. The anomaly in turn suggests a possible subsurface structure. Thus even though surface evidence alone may not be conclusive in the interpretation of subsurface structure, it may provide clues and stimulus for exploration (Alliger, 1955, p. 183). However, Wheeler and Smith (1952, p. 112) cautioned that " * * * strong deformation, periodically rejuvenated, is restricted to the mobile belts * * *," and structures farthest away from maximum deformation are " * * * therefore more difficult to infer from physiographic abnormalities at the surface * * * that without the genetic background of those events in the geologic history of the tectonic province responsible for surface and subsurface indications of structure, photogeology may be unfavorably speculative."

FOLDS

Folds may be expressed on aerial photographs by the distribution of bedding, by drainage characteristics, by topography, by distribution of soils, or by combinations of these criteria. The surface manifestations of folded or domed structures thus may range from obvious, where direct surface expression of dipping beds is present, to subtle, where subsurface structures are reflected only indirectly by physiographic criteria.

BEDDING

Many folded structures can be delineated readily because bedding is clearly expressed at the surface. Particularly in areas where rocks are well exposed and structural deformation has been mild, beds may be clearly defined by photographic tone together with topographic relief or hogback landform (figs. 90, 91, and 92); strike and dip of beds are easily determined and the structure delineated from the distribution of beds (see also p. 19).

In areas where bedding may be obscured by low plant and grass vegetation, differences in vegetation together with slight topographic relief changes, enhanced by vertical exaggeration of the stereoscopic model, may permit bedding to be delineated and struc-

tures to be structure contoured (see fig. 40 and p. 6).

DRAINAGE

In areas where bedding is largely obscured, for example by vegetation or surficial materials, stream patterns, anomalies, or textures may be helpful in determining dip slopes and outlining folds. In some areas dip-slope streams have a coarse-textured arrangement in contrast to the fine-textured arrangement of back-slope streams (fig. 79). These textures probably reflect coarse-grained and fine-grained rocks, respectively. The distributions of such textures in turn may suggest the location of structural axes.

In many areas stream adjustment to structure will result in a sweeping curve of the stream particularly across a structural axis and around the nose of a plunging fold; the convex side of the curve indicates the direction of anticlinal plunge (figs. 81 and 90). But such curves may also develop on dip slopes and thus not be indicative of the location of a structural axis. This situation may prevail where anticlinal structures are breached into softer material. Streams developing on the more resistant dip slope of the structural flank may curve on that flank and along soft interbeds, and not across the axis of the structure (fig. 93). Such a condition would probably be most pronounced during the mature phase of the geomorphic cycle. In geomorphically young areas streams may not have had sufficient time to adjust to folded structures, and may have a tendency to follow joints or preexisting faults (Howard, 1940, p. 195). In areas where stream pattern or anomaly is the primary surface reflection of underlying structure, as in some jungle-covered areas, other criteria, such as vegetation pattern, should be sought to corroborate the location of a structural axis suggested by stream characteristics.

Stream patterns or anomalies are undoubtedly the most useful indirect evidence of subsurface structures in many areas. This is especially true for coastal areas of low relief, many interior basins, or areas of dense vegetation or other surficial cover. Tator (1951, 1954) and DeBlieux (1949) discussed the structural significance of drainage anomalies in the coastal region of the Gulf States; in these low, swampy areas of aggradation it is important to establish the drainage norm by studying the drainage characteristics over a large area. Deviations from this norm may give the first indication of a structural anomaly. DeBlieux (1949, p. 1259) described abrupt locally restricted changes in drainage considered to be the result of subsurface structure. Over the Lafitte field in Louisiana a relic tributary of the Mississippi River forms two

sharp meander bends, although for miles upstream and downstream from this area, the stream channel is simple and straight. Over the Scully dome " * * * two relic distributaries of Bayou Lafourche followed simple courses, but suddenly changed to an anastomosing pattern over the dome, then resumed simple courses south of the structure." (DeBlieux, 1949, p. 1259.)

Structural implications of stream pattern or anomaly may be corroborated by other geomorphic evidence. Over the Lafitte field the presence of distinct remnants of natural levees on either side of the channel, the only such ridges over the length of the relic course of the stream, was considered significant supporting evidence of underlying structure (DeBlieux, 1949, p. 1259). The levee-ridge remnants presumably were held up by subsurface structure as surrounding areas subsided.

In a study of tonal and textural anomalies in west-central Texas DeBlieux and Shepherd (1951) described anomalous compressed meanders over structural highs. In the same area annular and radial drainage patterns and stream deflections in the flank areas were important criteria that supported an interpretation of subsurface structure (fig. 94). The importance of abrupt changes in direction of streamflow in relation to possible subsurface structures has recently been emphasized by Buttorff (1958) and Elliott (1958), based on work in the Powder River Basin, Wyoming. Such deviations from the norm for an area commonly stand out when a separate drainage map of an area is studied (see fig. 9) or when stereoscopic models are viewed pseudoscopically (see p. 5 and fig. 95).

In areas of aggradation and active subsidence it is to be expected that abnormal drainage characteristics rather than any specific drainage pattern might be indicative of subsurface structure. The combination of emergence, due to recent rise of salt plugs, and subsidence of the general coastal-plain area is responsible for many of the anomalous drainage characteristics of the coastal area of the Gulf States; such characteristics are anastomosing stream segments, abruptly widened levee ridges, or abrupt changes in direction of streamflow.

In areas of active degradation, patterns of drainage rather than abnormal drainage characteristics can be expected to be indicators of structure. However, Wheeler and Smith stated (1952, p. 82) that the analysis of stream pattern with regard to structure—which they called "creekology"—is somewhat outmoded as a photogeologic procedure; they implied that

anomalies in drainage characteristics may be far more important than specific drainage patterns. However, drainage pattern may actually be anomalous with respect to the drainage norm for an area; such examples of drainage patterns have been found along the northwest coast of Alaska on the Arctic coastal plain. Here, in an area of northward-flowing streams, slight topographic highs have resulted in radial-dendritic drainage patterns, which outline areas of subsurface structure (fig. 96). Commonly no other surface expression of structure is present. Because of low relief, outcrops are few.

TOPOGRAPHY

The presence of topographic highs has been significant in locating subsurface folds or domal structures even in many areas where relief is very slight. Many of the "islands" of the coastal area of the Gulf States are surface expressions of salt domes. Topographic features such as natural levees, which represent areas of higher ground only a few feet or tens of feet above the delta or flood plain, are also significant interpretation criteria in the search for subsurface structure (Tator, 1951). Tator reported (1951, p. 717) that " * * * cheniers and natural levees * * * provide linear patterns of higher ground supporting distinctive vegetation growths." These higher areas are also favored for cultivation. According to Tator (1951, p. 717) "Tonal contrasts in the photographs are the major keys used for recognition of landscape features of extremely low relief, such tonal variations being largely the result of soil and vegetation differences." The significance of low relief, is shown by DeBlieux's description (1949, p. 1254) of Felicity Island, a 2-mile-long natural levee ridge separated by several miles of marsh from the area where the levees normally could be expected to die out. The preservation of the "island" in an area of active subsidence has been attributed to local subsurface structure. Abrupt widening of levees on one or both sides of a channel, in areas of subsidence, also has been noted over subsurface domal structures (DeBlieux, 1949, p. 1254, and fig. 2, p. 1255); widening of levees may be due to other causes, such as coalescence of two levees, however, and this feature of the flood plain must be interpreted carefully.

In a study in northern Alaska, Fischer (1953) used topography as the principal interpretation criterion in locating the Square Lake anticline. The area is a treeless waste of low relief that is underlain by permafrost; tundra grasses cover the region, and no bedrock is exposed. Fischer (1953, p. 208) reported that the original photogeologic study showed small hills in the area elongate in the same direction as the regional

FIGURE 9.—Drainage map of area shown in figure 94.

Radial drainage over structure, *A* of figure 94, stands out on the drainage map which is unobscured by the abundant details of the photograph. Note that the radially draining streams flow into larger streams that have an

nular pattern around the structure. Stream deflections, as at *D* in figure 94, are commonly more readily observed on the separate drainage map or in pseudoscopic view of the model (see fig. 95).

structural trend. Normal to this trend other elongate hilltops sloped in the direction of the inferred dip of beds. Also, streams flowing in the dip direction had a slightly less well developed dendritic pattern than those flowing opposite to the dip direction. There also appeared to be a correlation between slopes of the tops of cut banks and the direction of dip. Plotting of all such data gave a consistent apparent structural pattern—a plunging anticline—of unknown reliability. A subsequent seismic survey corroborated the photogeologic interpretation.

SOILS

In some areas devoid of outcrops, soil patterns or soil distributions may be useful in delineating or suggesting structures. Both Woolnough (1934b, p. 221, 224) and Christensen (1956, p. 858–859) cited examples of the usefulness of aerial photographs in this regard. Wheeler and Smith (1952, p. 106) stated that contrasts in soil tone accentuate unusual drainage relations on the northern flank of a structure in the southwest Maysville area, Oklahoma; and in southwestern Alabama differences in cultivation pattern reflect relief and soil characteristics by which geologic units of Tertiary age beneath younger unconsolidated materials can be differentiated.

DeBlieux and Shepherd (1951, p. 98) described tonal and textural anomalies in west-central Texas that resulted from differences in soil types, soil-moisture content, and erosional characteristics. They cited an anomaly at Salt Fork on the Brazo River where “* * * dark and coarsely hummocky surface strongly contrasts with the lighter color and finer texture of the surrounding surface * * *” (DeBlieux and Shepherd, 1951, p. 98). The anomaly was strikingly similar to that of a reef producer in Scurry County. DeBlieux and Shephard (1951, p. 88) emphasized that how a structure forms is unimportant in a study of tonal, textural and other anomalies, because the surface evidence is identical, whether the structure has resulted from upward movement, differential downwarping, reef or residual topography, or combination of these features; it is important initially that a surface anomaly can be recognized.

FAULTS

Faults are significant in the geologic interpretation of petroleum areas because they may be deep seated and of major importance in localizing oil accumulation. Where faults are genetically related to structures that may be oil bearing the distribution pattern of faults may be of considerable use for interpreting the locations of those structures. The many surface expressions of faults are described above (p. 21).

Desjardins (1952, p. 82) stated that surface fault

and fracture lines, expressed as lineations on aerial photographs, form patterns that bear a definite relation to deep-seated salt domes and to subsurface faults of the Gulf Coastal Plain. Disturbance centers, believed to be underlain at depth by salt domes, may be indicated by the fault patterns, shown on photographs as “Sharply curving lines which are strikingly concentric” or as “Prominent transverse lines radiating usually from some marginal point rather than from the center of the structure” (Desjardins, 1952, p. 82). Desjardins believed that such fault patterns were the result of continuous application of small stresses caused by rising salt masses rather than an accumulation of stresses that would produce large amounts of movement; he also felt that faults probably would form in interdome areas as well as over the domes. The genetic significance of the fault pattern is thus critical if distribution of faults is used as a basis for locating the dome itself. Desjardins (1952, p. 83) made a strong distinction between surface expressions of faults, which he associated with deep-seated domes, and other criteria, such as topographic expression, widening of natural levees, and looping of stream channels, which he associated with shallow-seated domes.

Although most interpretations of faults are based on qualitative characteristics of observed data, such as the dislocation of correlative beds, or the contrast in light and dark photographic tones on opposite sides of a straight line, a quantitative approach to such studies may provide additional useful data. On the basis of azimuth-frequency studies Blanchet (1957, p. 1748) suggested that structural and stratigraphic anomalies in some areas may be located by a statistical analysis of fractures, which he defined as the generally abundant, natural lineations discernible on aerial photographs. The basis for analysis is a comparison of local deviations in the statistical mean direction of fracture sets with regional norms for each fracture set. Regional norms are first established by plotting fracture-azimuth frequency diagrams of the region involved. Then statistical mean directions of fracture sets are determined by analyzing samples within circular areas centered at relatively small horizontal intervals of a few miles. These local mean directions are in turn studied for local deviations which are entered into empirical equations that yield structure-intensity values. These structure-intensity values are then contoured, to form a structure-intensity map, which may reflect structural anomaly. The structure-intensity map is supported by a fracture-incidence map, prepared in contour form, and by an analysis of drainage characteristics of the area in question. Blanchet applied this method to a study of petroleum structures.

FACIES

Although the widest application of aerial photographs in petroleum geology has been with regard to structural traps, a study of aerial photographs may contribute to the location of stratigraphic traps, particularly if photogrammetric measurements of formation thicknesses can be made at many points within the stereoscopic model (see p. 59-60). From a qualitative standpoint it can be seen in figure 97 that a rapid loss of sandy section can sometimes be detected on aerial photographs. Such "shaling" or loss of sandy section due to facies change may be important in the search for stratigraphic traps and in some areas it may be measured photogrammetrically. In other areas well-defined formational units may thin or thicken without facies change, but this also may be significant in regional studies with regard to stratigraphic traps (Christensen, 1956, p. 861, fig. 6). Measurements of stratigraphic sections needed in such studies commonly can be made from aerial photographs.

REGIONAL STUDIES

The significance of aerial photographs in regional petroleum studies is widely recognized, but very little information is present in the literature with regard to this phase of photograph use. Not only may measurements be made from aerial photographs with regard to strike, dip, stratigraphic thickness, and closure, but the regional view of the mosaic or small-scale photographs permits a continuity of photographic criteria that may be of structural or stratigraphic significance. Overall geologic relations are brought together, and areas where detailed study is needed may be indicated. However, the limitations of the photogeologic technique must be constantly borne in mind. As Wheeler and Smith (1952, p. 112) pointed out, the validity of the technique " * * * depends a good deal upon the human element and the utilization of all applicable geologic data." They warned that " * * * the student of photogeology may * * * become overly impressed with geometric design of lines, masses, and tones so that, in the absence of understanding of the tectonic history he may find compatible alignments of stream courses, structurally inexplicable lineations or shapes and soil patterns that are not consistent with the known or expectable products of diastrophism" (1952, p. 112). An emphasis on regional study is indeed justified, however, if maximum use is to be made of aerial photographs, and this is true whether photographs are used in long-range exploration programs, as in reconnaissance mapping of broad basin areas, or in the ultimate study of local structures.

INTERPRETATION OF AERIAL PHOTOGRAPHS IN
SEARCH FOR ORE DEPOSITS

The search for ore deposits, similar to that for petroleum, requires favorable host rocks or structures, or both, and it is therefore necessary to determine the general lithologic character and distribution of rocks and associated structures as a basis for carrying out a mineral survey of an area. Aerial photographs may contribute geologic data not only with regard to the fundamental guides of lithology and structure in ore search, but they also may reveal details of physiography, which may be an important ore guide in the search for placer deposits. Botanical guides to ore bodies may also be detected on aerial photographs of some areas, although little work has been done in this field.

STRUCTURAL GUIDES

Where fractures have been significant in localizing ore deposits aerial photographs may reveal significant structural data relating to trends and offsets of fractures, even in areas where surficial cover is extensive. This is due in large part to the great variety of criteria suggestive of fractures (see p. 21). In many areas it is possible to determine spatial relations of sets of fractures, and to infer the relative ages of the fractures from the aerial photographs, although results of field study are necessary to determine the significance of the patterns.

Aerial photographs are presently most useful in study of those ore deposits associated with fractures. In many mining districts where mineralized fractures form a vein pattern that is repeated throughout the district, an analysis of the fracture pattern and distribution may provide significant data in the search for new ore bodies. Reed (1940) described the use of aerial photographs in a mineral-deposits study of the heavily timbered Chichagof mining district of Alaska where gold-bearing quartz veins are associated with faults and shear zones (see fig. 99). There the faults are commonly expressed as depressions owing to greater erosion of soft material from fault zones (see also Twenhofel and Sainsbury, 1958, p. 1433). Reed (1940, p. 44) stated that many faults of moderate surface expression would probably have been overlooked on the ground, and that many faults of weak surface expression were seen only on aerial photographs. Joliffe (1945, p. 604), in a discussion of photogeologic prospecting in the Yellowknife area of Canada, noted that some of the largest gold-ore bodies " * * * lie in strong shear zones that are marked by rather distinctive gullies in relatively massive, resistant volcanic rocks." Many of these shear zones and other lineaments are conspicuously shown on aerial photographs.

Gross (1951) pointed out that in the glaciated Dryden-Kenora area of northern Ontario and the Goldfields area of northern Saskatchewan, Canada, there are many linear features seen on aerial photographs but that only certain ones represent faults. He devised a scheme of statistical analysis to show the likelihood that certain linear trends were faults (see p. 21). Concentration of prospecting along these linear features in the Goldfields area resulted in discovery of pitchblende deposits.

Because faults commonly are interpreted readily from aerial photographs, photogeologic study may aid in locating extensions of faulted ore bodies. Faults that offset an ore body may show an orderly spatial arrangement, and information regarding direction of displacement may be extrapolated to similar faults whose displacement is masked by vegetation or surficial debris. Willett (1940) found that aerial photographs provide significant information on the location of faults cutting the Invincible Lode, a gold-quartz deposit in the Glenorchy district of New Zealand. The photographs strikingly show the offset of a lode east of the Invincible Lode by a series of parallel faults, which suggest that similar conditions exist at the Invincible Lode where the evidence is not as readily observed because of surficial debris. In the Invincible Lode area one major stream flows parallel to the strike of the faults, and a second stream is deflected along a fault for about 1,000 feet, then bends back to its old course; the direction of deflection also indicates the horizontal direction of displacement of the quartz lode. The pattern of displacement, based on photogeologic evidence together with ground evidence, suggests the location of faulted extensions of the lode.

Major anticlinal and domal structures, readily interpreted from aerial photographs of many areas on the basis of drainage characteristics or strike and dip patterns, are with notable exceptions of relatively little importance in ore search. Where folds have been a factor in localizing ore, as in some metamorphic rocks, they commonly are too small or the geology too complex for existing aerial photographs to provide useful guides in prospecting.

LITHOLOGIC GUIDES

Lithologic guides may be considered from the standpoint of the parent and host rocks, or from the standpoint of mineralized or altered zones, which are more appropriately termed mineralogic guides. Photogeologic interpretation of rock types (see p. 16-19) may outline broad target areas of favorable parent and host rocks (fig. 100). Lueder (1953, p. 823) suggested that various locations can be rated on the basis of

favorable photogeologic evidence; the most favorable area would become the prime target area for further investigation. Where some local field criteria are available, specific ore-bearing formations may be traced on photographs (fig. 98). At Ross Lake, Canada, the fact that rare-earth-bearing pegmatites of small areal extent were recognizable on photographs was a major factor in the discovery of certain tantalite deposits (Joliffe, 1945, p. 604).

The use of color aerial photography will increase many times the amount of lithologic information that can be obtained from a photogeologic study. This additional information will contribute not only to the reliable interpretation of host or parent rocks, but may permit local guides, such as alteration zones, to be readily recognized. In a study of the hydrothermally altered volcanic terrain near Tonopah and Goldfield, Nevada, information obtained from reversible-type color transparencies was contrasted with data obtained from thin sections of rock types. Kent (1957, p. 868) stated that "In both areas a general correspondence between coloration and alteration was observed. Zones of different coloration within a lithologic unit represent different stages of alteration. Colors of rocks in early stages of alteration are useful in recognizing lithology, but highly altered rocks have the same color within several different lithologic units. The colors associated with highly altered rocks are easily recognized on color aerial photographs; thus their distribution and their relationship to structural features can be studied." In addition Ray (1958, p. 37) wrote that "In one area of altered andesites a pale green color on color aerial photographs was found to represent an intermediate stage in the alteration resulting from partial silicification, with pale green chalcedony, and deuteric alteration and later oxidation of iron opaques. A light color in another zone was found to result from brecciation of dacite and attendant alteration to carbonates. A rather intense orange color was indicative of highly altered zones in all localities observed. However, the orange coloration did not indicate the rock type involved nor the type of alteration present, but rather was the result primarily of weathering of iron minerals following their partial breakdown by deuteric alteration."

PHYSIOGRAPHIC GUIDES

Some ore deposits are topographically expressed or are related to structures, rock types, or surficial deposits that are so expressed (fig. 102). Hence, topography may be considered a guide in ore search, although it does not by itself indicate the presence of ore. Because fractures commonly are topographically ex-

pressed as rectilinear depressions, a possible physiographic guide to ore as interpreted from aerial photographs may be said to exist in many areas. Where fractures have been mineralized, and the vein filling stands in relief, topography may be a useful guide in ore search. However, many mineralized veins are poorly resistant to weathering and erosion, and occur as topographically low areas.

Where topography results in a photographic texture it may be possible to delineate areas of favorable host rocks, as the paraschists in Surinam (Zonneveld and Cohen, 1952, p. 155). Grantham (1953, p. 336) pointed out that in the wet Sierra Leone area of Africa, the " * * * sharp change in topography from linearly arranged hills, controlled by schist and migmatite, contrasts with the irregular features of structureless granite."

An analysis of the physiography of an area may provide significant information, particularly in relation to placer deposits. As many placers have a complex history, it may be necessary to work out the alluvial history of a valley or valley system for maximum information in locating placer pay streaks. The arrangement and positions of old stream channels may be interpreted from meander scars, oxbow lakes, and different terrace levels that are commonly seen on aerial photographs. Photographs also may provide gradient measurements of present or past streams; this information may be significant inasmuch as placer concentrations occur especially where stream gradients flatten.

Buried stream channels, also the site of some ore deposits, may be interpreted from photographs of some areas on the basis of topographic expression (fig. 101). In many parts of the western Sierra Nevada, Tertiary stream valleys have been filled and gold-bearing gravel buried by younger lava flows. The greater resistance of the lava flows compared with the surrounding rocks has resulted locally in sinuous cappings of volcanic rocks that stand above the present-day stream system. Table Mountain, California (Loel, 1941, p. 384, 386-387), is an outstanding example of basalt capping auriferous gravel of a buried channel.

The location of stream-channel deposits recently has received wide attention in the search for uranium deposits on the Colorado Plateau in Western United States. There the Triassic Shinarump member of the Chinle formation is thicker in channels cut in the underlying Moenkopi formation, which is also of Triassic age. Some channels can be observed directly on aerial photographs (fig. 44); others may be inferred from isopach measurements, which in some areas may be obtained from aerial photographs. (See p. 58-59). The uranium is associated with carbonaceous materials,

largely plant remains, scattered throughout the channels.

BOTANICAL GUIDES

Much field and laboratory work has been accomplished with regard to plant distribution and plant concentration of certain elements as indicators of ore. Little has been done, however, on plant characteristics or associations that may be observed or interpreted from aerial photographs, and herein lies a field of research that has much potential. There appear to be three aspects of botanical study from aerial photographs that may contribute to the location of ore deposits. These involve (a) color differences in vegetation brought about by concentration of certain chemical elements, (b) species differences or absence of vegetation owing to concentration of certain chemical elements, and (c) distribution of vegetation suggesting favorable structures or rock types. Color differences in vegetation, due to mineral and chemical concentrations, that may be reflected on aerial photographs have received almost no attention, and offer an interesting field of study. Species differences or lack of vegetation has likewise received little attention in ore search, although Walker (1929, p. 50-51) noted that air search was made for "dambos" as indicators of copper deposits in central Africa. Dambos are open spots in the bush cover, where vegetation does not grow because of the concentration of poisonous copper salts in the soils. Walker noted that the Roan Antelope copper deposit was marked by such a dambo, although the deposit extended beyond the limits of open area. Identification of species from color differences due to concentrations of certain chemical elements may be particularly amenable to detection on color or other special aerial photography.

Plant and tree distribution may be useful indicators of structures or of rock types favorable to ore deposition; vegetation distribution may reflect physical characteristics of the rocks, such as porosity or presence of fractures, although some rocks, such as limestone, may be preferentially covered by a certain type of tree because of chemical concentrations in those rocks (see fig. 72) rather than because of physical properties. Or vegetation may grow preferentially or trees grow higher and be aligned along a fault or shear zone, which might in turn be a favorable site for ore deposition (see fig. 71). Such indirect guides in ore search contrast highly, however, with color or species differences, which might suggest more strongly the presence of ore minerals.

Levings and Herness (1953, p. 456-457) stated that heavy timber growth in the Corbin-Wickes area of Montana shows a preference for unaltered quartz mon-

zonite, which has a darker photographic tone than the surrounding andesite and dacite; ore occurs in the volcanic rocks. Zonneveld and Cohen (1952, p. 153) mention that vegetation differences permit photographic differentiation of the clay savannahs and sand savannahs of Surinam, South America. Bauxite production at Surinam's Billeton mine (Hemphill, oral communication, 1958) is from a clay area, and hence it is important to know the distribution of such clay areas.

INTERPRETATION OF AERIAL PHOTOGRAPHS IN ENGINEERING GEOLOGY

Aerial photographs have been used for many years to provide topographic and land-use information in locating routes for pipelines, highways, or other rights-of-way, but only in recent years have photographs attained wide recognition as a source of geologic information for engineering purposes. Many kinds of geologic information for engineering use may be obtained from aerial photographs. These include (a) identification and location of soil materials, particularly granular materials, which would provide suitable foundation sites for industrial and airport developments, or highway rights-of-way; (b) identification and location of clay and clayey silt soils, which would have detrimental properties with regard to building, airport, and highway sites; (c) location of aggregate materials; (d) delineation of areas that may be underlain by permafrost; (e) interpretation of distressed conditions in landslide areas; (f) analysis of structural geology in areas of tunnel, dam, and reservoir sites; and (g) location of sample areas for detailed investigation of soil and rock materials.

SURFICIAL MATERIALS

Surficial materials generally are interpreted in terms of gross physical characteristics, rather than the detailed physical characteristics used by the pedologist. Knowledge of the gross physical properties is sufficient for many reconnaissance studies in engineering geology. Indeed, it is the grouping of several pedologic soil types into a few classifications that permits aerial photographs to be of significant engineering use. In the preparation of soil-engineering maps from agricultural reports of an area in Illinois, Thornburn (1951, p. 91) was able to reclassify 99 different pedologic soil types into 13 engineering groups. Lueder (1951) described the use of aerial photographs as a major tool in preparing soil-engineering maps.

The inability to interpret fine details with regard to physical characteristics of the soil thus does not preclude the use of aerial photographs in many engineer-

ing geology studies. From the standpoint of engineering significance a granular material, for example, which exhibits certain diagnostic photographic characteristics such as coarse-textured drainage, will generally react favorably to drainage, compactability, and other engineering tests, regardless of whether it is a residual granular material that has resulted primarily from weathering in place or whether it is a transported gravel derived from different rock types. However, Jenkins, Belcher, Greeg, and Woods (1946) pointed out exceptions to the general thought that photographic characteristics common to granular materials always signify suitable granular materials for engineering purposes. For example, the soil profile of well-drained limestone has a granular texture due to aggregation of clay particles into lumps. The surface drainage may be coarse textured; but the soils break down on compaction and react as plastic soil material, and not as a granular material (Jenkins, Belcher, Greeg, and Woods, 1946, p. 80).

Where pedologic data are already available they may be very useful to the engineer when interpreted in terms of engineering test data (fig. 4). Indeed, certain soil mechanics tests by the engineer, such as plasticity or soil-texture tests, are similar to those used by the pedologist. Greenman (1951) suggested that the pedologic method can become the nucleus around which aerial photo interpretive and field geologic information can be accumulated. But Eardley (1943, p. 567) pointed out that "In many places conditions unfavorable for the development of a normal soil, such as rugged mountains, wide sandy plains, or swampy basins may cover rather large areas. The important construction materials in such places may be better interpreted as a result of geological processes than from the standpoint of a soil classification * * *."

GROUND CONDITIONS

The interpretation of ground conditions probably has received more attention in recent years than any other engineering geology application of aerial photographs. Much of the literature concerns reconnaissance studies of soils in general and granular materials in particular; granular materials are essential for building sites and highway and airport development (Jenkins, Belcher, Greeg, and Woods, 1946; and Purdue University, 1953). Special attention also has been given to photointerpretation of permafrost conditions in northern latitudes.

With regard to highway engineering, Belcher (1945, p. 144) stated that "* * * the soil problem resolves itself into two parts, one in which the soil in place is satisfactory as subgrade, and the second, where the soil is unsuitable. In areas of unsuitable soils some form

of improvement, by stabilization or insulation, is required. Insulation involves the economic location of granular materials in the form of rock to be crushed, cinders (volcanic), or sand and gravel * * *. Inasmuch as sand and gravel or other granular deposits exist to some extent in nearly every county in the country the significance of soil patterns indicating granular materials is of considerable economic importance to engineers." In fact, a large percentage of construction and maintenance expenses are in the costs of sand, gravel, crushed rock, and similar materials. As a tool for interpreting areas of gravel, sand, silt, and clay, aerial photographs offer an inexpensive and rapid method of reconnaissance, and according to Schultz and Cleaves (1955, p. 370) "* * * planning and exploration for large engineering projects should almost never be undertaken without a thorough study of aerial photographs of the region * * *."

Photointerpretation of surficial materials must consider not only the surface expressions of these materials but also the geologic factors reflecting the origin of these materials. A knowledge of the origin of materials permits inferences as to what kind of materials can be expected in an area, and in what locations with respect to other geologic features. Field-sampling programs also could be based on the analysis of the photo-geologic data, and subsequent mineralogic and related studies by the engineering geologist could provide the soils engineer with information that would eliminate the need for many of the soil mechanics tests now performed as part of the routine laboratory analysis of all soil samples.

ELEMENTS OF SOIL PATTERN

The surface expressions of granular and other soils materials have been termed collectively the "soil pattern." The soil pattern consists of several elements of which the most important ones for nonpermafrost areas are considered to be landform, drainage, erosion, relative photographic tone, and color; vegetation cover and land use may also be significant (Belcher, 1944, 1945, 1948; Jenkins, Belcher, Greeg, and Woods, 1946; Frost, 1946; Mollard, 1947; Hittle, 1949; and Purdue University, 1953). Schultz and Cleaves (1955, p. 371) considered that "interpretation of soils by means of aerial photographs rests largely on the interrelationships of soils and geomorphic features"; consequently landform is considered by some to be the most important element in photointerpretation of soils. Landform, however, is only one element of the soil pattern and it is clearly evident that the association of several elements of the soil pattern will provide the greatest amount of information from aerial photographs.

Landform

Identifying the landform commonly identifies the natural process that formed it, and commonly limits the type of soils or soil characteristics that can be expected. The emphasis on landform is probably valid in reconnaissance soils investigations where broad areas of several different landforms are studied and mapping is at a small scale. But where detailed engineering information is needed, as in foundation studies, it is likely that the area of study will be within one landform, mapping will be on a large scale, and other elements of the soil pattern, such as differences in relative photographic tone, which may reflect soil-moisture content, will be of prime importance.

In small-scale mapping the emphasis on landform is probably warranted particularly for constructional landforms of transported materials, such as sand dunes, river terraces, alluvial fans, and many glacial landforms, all of which have distinctive shapes, although not necessarily unique (see figs. 52, 55-57, and 104); here the transported soil materials make up the landform. In contrast residual soils associated with destructional landforms may be more difficult to interpret from aerial photographs, for here the parent rock makes up the landform, and the significance of soils rests in part on the subjective interpretation of rock types. However, the interpretation of other elements of the soil pattern with regard to physical characteristics of soils are just as valid for residual as for transported materials; the engineering significance of many residual soil areas can be interpreted readily from aerial photographs on the basis of these other elements, such as drainage and erosional characteristics (figs. 63 and 65).

Drainage characteristics

Highly permeable soils will have good drainage regardless of their origin, provided that topographic positions will permit draining. In well-drained soils surface drainage normally will be coarse textured or even absent (figs. 49, 52, 66, 104, 106, and 108); in soils of low permeability drainage will normally be fine textured (fig. 63) or ponds may be numerous (figs. 57 and 66). The presence of fine- or coarse-textured drainage in surficial materials, like that in bedrock (p. 16), is primarily related to the relative resistance of the different materials to erosion, and hence related to permeability and grain size. Coarse materials characteristically are resistant to erosion, are permeable, and have a coarse-textured drainage; fine materials commonly are less resistant to erosion, are impermeable, and have a fine-textured drainage. These relations are significant in the interpretation of engineering soils from aerial photographs because drain-

age texture can be readily observed. However, exceptions to these relations may exist, as with loess, which is commonly characterized on aerial photographs by a relatively fine-textured drainage (see figs. 105 and 106); yet, loess in its natural environment is generally considered well drained internally.

Flow or channel markings, for example on terraces, indicate that the material was deposited by running water and further suggest that the material may be granular. Frost (1946, p. 121) described flow markings in an area in the midwest as consisting of light and dark streaks usually parallel to the direction of flow. The light streaks are ridges of sand or fine gravel that are probably sand and gravel bars; the dark streaks are fine clay or organic material deposited in depressions that once contained standing bodies of water. Frost (1946, p. 121) stated that "The chief significance of such markings lies in the fact that they suggest stream deposition and in order to have stream deposition at such elevated positions and occurring on * * * a large scale, there must have been large volumes of swiftly flowing water. Since swiftly flowing water allows only coarse material to settle, the terrace must contain a large percentage of gravel." It may be debatable that channel markings always indicate swiftly flowing water, but where some doubt exists other elements of the soil pattern may reveal the character of the terrace material.

In broad areas of aggradation, such as the Mississippi embayment, drainage characteristics revealed by aerial photographs are significant to the engineering geologist, as different soil characteristics are associated with the several features of valley alluviation. For example, backswamp areas contain clay and silty clay of high organic content, whereas natural levees consist of silt, silty sand, and some silty clay (Fisk, 1944, p. 18, 20). The levees commonly " * * * provide linear patterns of higher ground supporting distinctive vegetation growths" (Tator, 1951, p. 717). Low areas may be swampy and also contain distinctive vegetation. Graveliferous deposits fill the old valleys and in turn are covered by various other deposits; sandbars contain permeable sand that grades downward into the gravel. The distribution of features of the flood-plain drainage may be significant in analyzing ground conditions and locating favorable engineering materials in highway, railroad, and airport development.

Erosional characteristics

Closely related to the drainage characteristics of a soil are its erosional characteristics; these are important in photointerpretation studies chiefly from the standpoint of gully erosion, which is controlled largely by the physical properties of the soil and especially by

cohesion. The usefulness of gully erosion characteristics in photointerpretation primarily involves the shape of transverse profiles, although longitudinal profiles may provide additional information. According to research workers at Purdue University (1953, p. 15-16) " * * * there are three basic gully characteristics which are associated with three major soil textural groups." Granular soils commonly develop sharp, V-shaped gullies that have short, steep gradients. Nongranular cohesive and plastic soils are generally indicated by uniform gentle gradient of gullies that extend well back into the upland, and by broadly rounded shallow V-shaped transverse profiles. The loess soils and sandy-clay soil exhibit U-shaped cross sections of gullies that have flat bottoms and low gradients.

Although there may be a general adherence of gully characteristics to the major soil textural groups, exceptions are not uncommon. For example combinations of the basic gully characteristics " * * * occur in 'layered soils' or in soils exhibiting a 'strong profile'". (Purdue University, 1953, p. 16), and compound gradients may develop. In addition to the steep or vertical slopes in deep gullies, windblown silt may develop silt pinnacles and catsteps or terracettes (Purdue University, 1953, p. 45). It has been pointed out (Purdue University, 1953, p. 27) that climatic environment under which gullies form is an important consideration; for example, soft clay shale in an arid region where flash floods may occur commonly exhibit abnormally steep slopes in contrast to clay shale in areas of uniform rainfall where such slopes are usually softly rounded. Under certain conditions, such as gravel capping on clay soils in the New Jersey coastal plain (fig. 108), gullies in the underlying clay soils may be steep and deeply incised, in contrast to the usual broad shallow transverse gully profile of the clay soil group in humid regions.

In permafrost areas different materials may yield the same cross-sectional profile. Gravel deposits cemented by ice may have vertical gully walls, or may have gullies that are asymmetric in cross section if one side is preferentially exposed to the sun and thaws at a faster rate than the shadow side. The insulating materials overlying frozen deposits also affect the rate of thawing and hence the erosional characteristics of gullies. Interpreted carefully, however, the erosional characteristics—gully cross section and gradient—may reveal useful information on texture and other engineering characteristics of the soil.

Photographic tone

On black-and-white photographs the significance of color must be interpreted in terms of relative gray photographic tones. Belcher stated (1948, p. 486) that

"Light color tones (grays) are usually associated with well-drained soils, while clays, principally because of their water-retention capacity, appear dark." Frost (1946, p. 122), in describing the mottled soils in Indiana, stated that mottling nearly always indicates gravel. The mottling is due to "dark areas" which are " * * * small clay-like pockets that have been formed by the normal weathering processes of the gravel-sized material" (Frost, 1946, p. 122). These pockets are depressions that " * * * act as small infiltration basins which result in a higher moisture content and a darker color pattern" (Frost, 1946, p. 122). This mottled soil pattern contrasts with that of the drift plains in other areas where light-toned patches of slightly higher and dryer silty soils adjoin lower areas of wet plastic silty clays. Somewhat similar mottled patterns have been described by Gwynne (1942, p. 202-205) from the drift plain in Iowa (see fig. 107). But light photographic tones also may result from lack of moisture, owing to lack of precipitation as in many arid regions, rather than because of good drainage, and thus tone may be of little significance in evaluating soil texture in some areas. Or light tones may be the result of topographic position, and it is probable for example that a " * * * sand dune on a sand plain in a humid region will photograph light in color against a dark background" (Purdue University, 1953, p. 26) not because of differences in soil textures but because of topographic position. Climatic conditions also influence the colors of soils, especially the residual soils, and dark color rather than light color may be associated with well-drained materials, as certain red soils developed from limestone (Jenkins, Belcher, Greeg, and Woods, 1946, p. 84). Yet, provided climatic conditions are considered and provided relative photographic tone is borne in mind, the generalization that light photographic tones suggest good drainage and dark tones poor drainage may be useful in the overall interpretation of soils with regard to moisture content. Where tone is due to moisture, infrared photography will result in strong tonal contrasts between soils of different moisture content.

Color

Color has been cited as a principal element of the soil pattern that may yield information on the texture and drainage character of the soil profile, but to date very little interpretive work has been done with color photography. Belcher (1945, p. 138) briefly mentioned experimental color photography taken in different parts of the United States and stated that "The value of color * * * lies in the added detail that it furnishes with respect to these two elements of the soil pattern" (that is, soil color and details of vegetative cover). It

would seem that color photography would reveal pedologic information significant in engineering evaluation of soils, especially the residual soils, which may be more difficult to interpret in general than transported soils, particularly from black-and-white photographs.

Vegetation

Vegetation as an element of the soil pattern has been considered one of the most difficult to interpret. It is known, for example, that certain trees, such as aspen, are tolerant of many different soils and soil conditions, but some types of vegetation are strongly influenced by soil type. Furthermore, vegetation may be influenced significantly by climatic factors. Where permafrost is close enough to the surface to affect tree and shrub roots the kind of vegetation that will grow may be restricted (see p. 37). Species identification may be difficult in any area unless large-scale photographs are available or unless pure stands are present. Nevertheless, vegetation may reveal significant information in engineering studies provided valid interpretations are made with regard to how vegetation is associated with soil textures, soil-moisture content, and topography; thus a knowledge of plant ecology is necessary if maximum information on soil conditions is to be obtained from aerial photographs. Willows, for example, indicate wet ground, poplar indicates dry ground, and jack pine implies sand and gravel beds (Belcher, 1945, p. 139). However, where abrupt changes in soil conditions exist, it is likely that vegetation changes will also occur (figs. 56 and 72), and areas needing further ground surveys may be easily delineated by inspection of aerial photographs without any basic knowledge of plant ecology. For example, stabilized sand dunes in interior Alaska can be easily delineated because they are marked by stands of dark-toned spruce (see fig. 56), in contrast to light-toned brush and grass of the interdune areas. This relation may be found where the topographically higher, well-drained sand of the dunes contrasts with frozen silty deposits of the interdune areas.

Where phreatophytes—plants and trees that obtain water from the water table—can be delineated (see p. 40), aerial photographs may provide significant engineering data because phreatophytes may choke overflow channels and thus increase the flood potential of some areas. Information pertaining to the downstream de-silting effect of phreatophytes with regard to dams and reservoirs may also be obtained from aerial photographs of some areas (see Robinson, 1958, p. 28-29). However, little interpretative work in this field has been done.

Land use

Land use may also reveal information on the soil conditions of an area. Belcher (1945, p. 142) reported that "Orchards thrive in well-drained locations and therefore, when observed on level ground, good sub-drainage is implied." Shallow drainage ditches in areas of little relief commonly signify plastic, poorly drained soils. Schultz and Cleaves (1955, p. 378) stated that in eastern France and western Germany " * * * rugged topography and associated sandy soils developed on sandstones are generally left in forest; the comparatively level topography and associated clayey soils developed on shales and limestones are cultivated * * *." On the flood plain of the Mississippi River the silty sand of the natural levees is cultivated primarily because of its topographic position above the lower backswamps. In parts of the Valley and Ridge province of Eastern United States the limestone areas commonly are farmed whereas shale areas may be left in forest.

PERMAFROST

Permafrost has a significant effect on engineering characteristics of soils of the far northern latitudes and has received considerable attention in recent years, particularly from the standpoint of photointerpretation (Cabot, 1947; Woods, Hittle, and Frost, 1948; Benninghoff, 1950; Frost and Mintzer, 1950; Frost, 1951; Sager, 1951; Black, 1952; Hopkins, Karlstrom, and others, 1955). Considerable disagreement exists, however, on the significance of photointerpreted data in the study of permafrost areas (see Black, 1952, p. 126-127, 129), although it is generally agreed that aerial photographs can be particularly useful in such studies. The following discussion of ground conditions in permafrost areas is taken from the work of Hopkins and Karlstrom (Hopkins, Karlstrom, and others, 1955), except as noted by specific references.

Muller (1947, p. 219) defined permafrost as "a thickness of soil or other surficial deposit or even bedrock, at a variable depth beneath the surface of the earth in which a temperature below freezing has existed continuously for a long time (from two to tens of thousands of years)." Muller (1947, p. 30) also stated that "From the standpoint of engineering, the content of ice in frozen ground is of paramount importance * * * [because] * * * thawing of this ice produces excessive wetting and undesired plasticity of the ground and renders it unstable and susceptible to settling, caving, and even flowing." Building foundations, highways, railbeds, and airport runways may be considerably damaged unless the presence of permafrost is taken into consideration and measures taken to eliminate or minimize the effect of the thawing that results from

the disturbance of the natural thermal regimen. Where bedrock or thick frozen gravel deposits that contain local drainage channels are the primary foundation materials, permafrost is not normally detrimental to construction.

Although aerial photographs are useful in the interpretation of areas that may be underlain by permafrost, criteria used for interpreting soil conditions of nonfrozen areas apply only to a limited extent to permafrost zones. Gully characteristics of an impermeable gravel deposit cemented by ice, for example, will not necessarily be the same as the characteristics of gullies in impermeable nonfrozen soils. Because of the altered permeability and porosity of soils owing to permafrost, erosional characteristics, as applied to the interpretation of nonpermafrost areas, may have little significance in the perennially frozen regions. Other criteria, such as the common landforms, although suggestive of type of material present, are of limited use in determining the presence or absence of permafrost. Few diagnostic indicators of permafrost appear to exist. More often than not the criteria are suggestive rather than indicative; they include distribution and type of vegetation, polygonal relief patterns, pingos, and features resulting primarily from thawing.

Distribution and type of vegetation

Distribution patterns of trees and shrubs commonly supplement topographic expression in recognizing landforms; these patterns may contribute indirectly to the interpretation of probable permafrost conditions based upon inferences concerning the age of the land surface, climate, and character of the underlying material. In addition, the type of vegetation may be useful in delineating areas where permafrost is likely to be present. Hopkins and Karlstrom (1955) reported that recognition of shallow-rooted species on aerial photographs aids in delineating the areas where permafrost is most likely to occur at shallow depth, and that recognition of deep-rooted species helps delineate areas least favorable for the formation or preservation of permafrost. Thus, black spruce may suggest areas underlain by permafrost at shallow depth, whereas tall willow shrubs and isolated pure stands of balsam popular on river flood plains generally indicate unfrozen ground. The distribution patterns of trees and shrubs, however, are most significant only when evaluated together with other information, such as type of landform, concerning permafrost distribution in the region under study.

Polygonal relief patterns

Polygonal relief patterns commonly can be identified on aerial photographs, but as they may be present

in both permafrost and nonpermafrost areas this criterion is not, by itself, always diagnostic in evaluating permafrost conditions; however, in conjunction with other features it may be very significant. Polygonal patterns may be divided into two broad groups: those formed by frost-stirring and those formed by contraction. The formation of frost-stirred polygons is favored by the presence of permafrost at shallow depth, but these polygons are not necessarily an infallible indicator of shallow permafrost as they are also known to occur where permafrost is absent or is at a considerable depth.

Contractional polygons are subdivided into low-center, high-center, and frost-crack polygons. Low-center polygons, one of the most dependable indicators of permafrost, are commonly found in poorly drained depressions. The presence of pools of water in the centers of some polygons is a diagnostic recognition feature, and it is common to find low-center polygons expressed on aerial photographs as dark-toned centers surrounded by light-toned marginal ridges (figs. 109–112). High-center polygons occur in slightly better drained areas than those in which low-center polygons are found; generally, the centers are relatively level, although they may be domed where frost is extremely active. In contrast to low-center polygons, drainage around high-center polygons is commonly concentrated in marginal trenches, and pools of water are present at trench intersections. Because of the high centers, these polygons are commonly expressed on aerial photographs as light-toned centers surrounded by dark-toned margins (figs. 40 and 109–112). Frost-crack polygons may be difficult to distinguish on aerial photographs, as they are similar to high-center polygons; they may be present in some areas where permafrost is absent.

Other relief patterns in conjunction with vegetation distribution result in striped slopes that are commonly present in permafrost areas (fig. 40).

Pingos

Pingos are rounded or elliptical steep-sided hills formed by the “downward freezing of a body or lens of water or of semi-fluid mud” (Muller, 1947, p. 59). They may be as much as 300 feet high. Fissures may develop along the axis of a pingo or radiate from the crest. Pingos usually are found in poorly drained areas and normally are readily distinguished on aerial photographs by their distinctive local landform (figs. 110 and 111); they are almost always a reliable indicator of permafrost, although locally they may be confused with erosional knolls or hills.

Features resulting from thawing

Two features associated with thawing are suggestive of the presence of permafrost. These are thaw lakes (sometimes called thermokarst lakes) and beaded drainage. Thaw lakes occur in frozen fine-grained sedimentary deposits that generally contain clear lenses and masses of ice whose volume is greatly in excess of the porosity of the unfrozen material. As this ice melts the ground subsides and forms a basin in which a thaw lake may accumulate (figs. 110 and 111). When caving is progressing, banks are ragged and steep or overhanging. Tilted trees known as “drunken forests,” along the margins of such lakes are indicative of active caving. In treeless areas active caving may be indicated by tension cracks parallel to the banks. Other indications of thawing, such as serrated margins of lakes, also may be present (figs. 109–111). The usefulness of thaw lakes as permafrost indicators, however, is limited by the difficulty of distinguishing on aerial photographs between active thaw lakes, relict thaw lakes, and similar-appearing lakes that are in no way related to permafrost.

Beaded drainage occurs particularly in perennially frozen peat and silt containing ice wedges; it is characterized by small pools connected by short water-courses that may be sharply incised (figs. 40 and 112). The pool banks commonly are steep as a result of thawing and caving of frozen materials.

Absence of permafrost

In areas of discontinuous permafrost it is not only desirable for the engineer to know where permafrost is present, but it may be equally important to determine where permafrost is absent. Certain hydrologic phenomena and elements of the soil pattern commonly indicate or suggest the absence of permafrost. For example, subterranean drainage in unfrozen zones within permafrost may be detected on aerial photographs of some areas. The recognition criteria are in part similar to those applied in evaluating soil conditions in nonpermafrost areas of the world. That is, streams may disappear into the bottoms of closed depressions or by percolating into a gravel-covered surface. In addition, the presence of dry depressions in permafrost areas may indicate locally well-drained areas, inasmuch as there is generally a source of water during the summer months. Such areas contrast with other areas of the earth's surface where dry depressions may be due to absence of precipitation or other immediate source of water. Locally unfrozen zones within permafrost areas may also be suggested by springs, which are commonly indicated by flood-plain icings; shown as flat, white surfaces on some aerial

photographs, or indicated by more luxuriant vegetation along a pronounced lineation or within a dark-toned area on low hill slopes. These unfrozen zones may be favorable as a source of ground water. In addition, because permafrost generally causes soils to be impermeable, drainage characteristics indicative of permeable materials (see p. 34) may be interpreted to mean lack of permafrost, at least in the immediately underlying materials. Certain tree species may also suggest absence of permafrost (see p. 37).

EROSION, TRANSPORTATION, AND DEPOSITION

LANDSLIDES

Natural movement or potential movement of materials is a significant consideration in many construction engineering problems. Foremost in this regard is the movement of soils and rock materials by landslides. Ritchie (1958, p. 67) stated that "All landslide investigations must start with recognition of a distressed condition in the natural or artificial slope * * *." Distressed conditions are commonly interpretable from aerial photographs. "The evidence for distressed conditions that may be present, or that may be induced, lies chiefly in evidence of movements, minor or major, that have already taken place or of geologic, soil, and hydrologic conditions that are likely to cause movement in the future" (Ritchie, 1958, p. 67). Geologic, soil, and hydrologic conditions signifying potential landslide areas include the presence of unfavorable geologic structures and rock type, prevalence of fine-grained materials, and an abundance of water or conditions that would permit access of water to fine-grained materials.

Because remedial measures for landslides or prevention of landslides are generally not only difficult but costly, avoidance of landslide areas is important in highway route layout. Existing landslides are commonly identified on the basis of landform (figs. 46 and 113). Liang and Belcher (1958, p. 70) stated that some landforms are more susceptible to landsliding than others, and thus identifying the landform is highly important. "Potential slides of the rockfall and soilfall type can commonly be foreseen simply by recognizing geologic conditions that are likely to produce overhanging or oversteepened cliffs" (Ritchie, 1958, p. 51). Basalt cappings underlain by easily eroded shale (figs. 53, 87, and 113) illustrate a condition where rockfalls may occur as a result of failure and slump in the underlying materials.

Movement of unconsolidated materials by flowage is likely to produce the most damaging landslides. Existing flows and slides (figs. 46 and 113) commonly have a "hummocky" surface. Landslide scars, where

soils and vegetation have been stripped off the bedrock, may be easily recognized on aerial photographs by the light photographic tone of the bedrock in contrast to darker tones of surrounding areas. Areas of potential flow of unconsolidated materials may be revealed by tension cracks or crevices, or suggested by the presence of seepage zones or springs, shown by dark tones of dense or luxuriant vegetation or by dark tones of the soil.

Ritchie (1958, p. 50) warned, however, that although aerial photographs are of significant help in developing the setting for detailed studies, they seldom contain the detail needed by the engineer to carry out preventative or remedial measures. The prime application of aerial photographs in landslide studies appears to be in interpreting ground conditions to determine areas that should be avoided in highway route layout and similar problems.

BEACH EROSION

In a shoreline study in California, Munk and Traylor (1947) showed that variation in wave height and refraction of waves along the shore was controlled in part by sea-floor topography. Where refraction causes a convergence of waves the rate of shoreline erosion may increase. Krumbein stated (1950, p. 203) that "Refraction diagrams are becoming an essential part of any study concerned with shore processes, and graphic methods have been developed for preparing them from hydrographic charts or aerial photographs." Photographs taken periodically of shoreline areas would also provide information, both qualitative and quantitative, in studies of erosion and deposition, which might thus be useful in planning remedial action against the eroding currents. In a study of shoreline erosion by the U.S. Army Corps of Engineers (U.S. Beach Erosion Board 1946, p. 13) aerial photographs taken in 1941 were compared with land surveys of 1836 to obtain rates of erosion along the shore of Lake Michigan. The rate of erosion plays a significant part in planning corrective measures for eroding currents.

BEDROCK

GEOLOGIC STRUCTURE AND TYPE OF ROCK

Because of the influence that faults may have on construction design and costs, it is important that faults be located and studied in the beginning stages of an engineering project. Aerial photographs may provide significant information in this regard as some faults are recognized from subtle expressions on photographs but are identified only with difficulty on the ground. The usefulness of photographs in mapping a proposed damsite in southeastern Alaska is shown in a

study of the Swan Lake area (fig. 114) where faults stand out in aerial view as conspicuous lineations, which are primarily reflections of rectilinear depressions on the ground. In a damsite study in Malaya, Alexander and Proctor (1955) used large-scale aerial photographs taken 750 feet above the ground. These photographs showed clearly the attitude and distribution of faults and joints in granitic country rock. In connection with the San Jacinto tunnel project in California, Henderson (1939) noted that aerial photographs revealed indications of unsuspected faults and corroborative evidence of those previously suspected. Fault locations underground were found to be close to that predicted from study of photographs.

In addition to showing faults, aerial photographs commonly shown dipping beds that are important in some foundation studies for pier and abutment location. Or dipping beds may indicate potential rock-slide conditions where the dip is in the same direction as the hill slope.

Lithologic characteristics of bedrock materials are also significant in many engineering problems, as in foundation work, or in locating road metal sources. Criteria useful for interpreting the general lithologic character of rock types from aerial photographs are discussed on pages 16-19.

INTERPRETATION OF AERIAL PHOTOGRAPHS IN HYDROLOGIC STUDIES

LOCATING POTENTIAL GROUND-WATER SOURCES

Little has been written on the interpretation and uses of aerial photographs specifically in hydrologic studies, although photogeologic techniques offer both practical and research applications in this field. Practical application of aerial photographs in hydrologic study are at present confined largely to assisting the geologic mapping in ground-water investigations, particularly in areas covered by surficial materials. As an aid in ground-water mapping, elements of the soil pattern are evaluated in terms of ground conditions, just as in many engineering geology studies (see p. 34-37). Thus, for example, coarse-textured drainage or absence of drainage may signify highly permeable materials (figs. 52, 66, 88, 104, and 105B; and p. 34-35) or the landform (figs. 52 and 104) may suggest the kinds of materials that compose it, which permits an evaluation of permeability and porosity and potential as a water reservoir. In addition, aerial photographs may reveal information directly suggesting the presence of water, such as a preferential distribution of vegetation at the margins of a gravel cap (see figs. 104 and 108). The type of vegetation in turn may permit inferences with regard to the general quality

of water. For example, salt cedar is tolerant of relatively high content of salt in water, whereas cottonwood trees are intolerant. Howe (1958) described briefly the use of aerial photographs with specific reference to locating possible water-bearing formations.

WATER-LOSS STUDIES

In a study of water loss caused by phreatophytic plants and trees, which take their water from the water table, Turner and Skibitzke (1952) used aerial mosaics and contact prints for delineating areas of different densities of phreatophytes. The areas were then measured by planimeter and used in conjunction with vertical foliage density, determined by field methods, to arrive at volume density to which water loss by transpiration for specific species could be equated. Data pertaining to tree species and heights were determined by ground methods. Turner and Skibitzke (1952, p. 67) stated that "The comparison between results obtained by air and by ground mapping led to the conclusion that the former offers a much faster and more accurate method, particularly in areas of dense growth." Further use of aerial photographs in collecting basic data for studies of water loss by phreatophytes could probably be made. For example, it may be possible to determine tree or plant species, especially when large-scale black-and-white photographs are available or where color photographs have been taken. In addition, for many areas where the ground surface can be observed through the trees, photogrammetric measurements may provide rapidly those height measurements needed in water-loss studies. For areal measurements of differing vegetation types or densities a simple dot-templet method may be useful (Wilson, 1949). Like many other studies, however, where vegetation and ground features must be observed, measured, and plotted, maximum use of aerial photographs will result from combined use of field and photogeologic methods.

OTHER APPLICATIONS

Aerial photographs as a tool in hydrologic studies provide a medium for obtaining basic data, such as cross-section profiles, linear, areal, slope, and volume measurements. Some of the suggested uses of photogrammetric techniques in hydrologic studies are: (a) for definition of channel size and shape of cross section to be used in studies of the effect of channel geometry in flood characteristics of streams; (b) for determining channel storage capacity used in flood-frequency correlations; (c) for definition of the three-dimensional sinuosity of natural channels to be used in studies of the rate of energy loss; (d) for definition of the geometry of bed roughness of alluvial channel

models (Thompson, 1958); (e) for measuring topographic characteristics of drainage basins such as stream slopes and drainage density; and (f) for determining areas of lakes and swamps in water-storage studies.

INSTRUMENTATION

Instruments in photogeologic study serve three objectives, namely, interpretation, measurement, and plotting of data. The instruments used thus may be photogrammetric or nonphotogrammetric—photogrammetry is the art of making reliable measurements from photographs. Usually different instruments are used for attaining each of the three objectives, as, for example, in using a stereoscope, parallax bar, and radial planimetric plotter, respectively. But all three operations may be combined in a single piece of equipment, such as the Kelsh plotter (fig. 18). Whether interpretation is done with a simple stereoscope and paper prints or with a precision stereoplotting instrument using glass-plate diapositives, the criteria of recognition, described in the first part of this paper, remain the same except insofar as scale and resolution of photographic details are involved. Both measurement and plotting are here considered as mechanical aids that provide quantitative information to be further used in geologic interpretation of an area, and instruments are discussed primarily with this objective in mind.

Measurement involves (a) the determination from aerial photographs of vertical and horizontal distances, which in turn are used to compute stratigraphic thicknesses, angles of dip, and other quantitative data of geologic use; (b) the direct determination of inclined distances, commonly the stratigraphic thickness of a formation; (c) the direct determination of angles of slopes or beds; and (d) other quantitative determinations of possible significance in geologic interpretation, such as light-transmission measurements.

Plotting primarily involves the orthographic positioning of geologic data from aerial photographs to base maps or compilation sheets. It also involves direct plotting of geologic data in cross-sectional views, and may include positioning data such as geologic contacts, which are not directly recognizable in the stereoscopic model, by use of the floating dot or spatial reference mark that is found in many photogrammetric instruments.

KINDS OF INSTRUMENTS

Many different photogrammetric instruments are available for making measurements and plotting geologic data to base sheets or cross-sectional profiles (see Fischer, 1955; Ray, 1956; Pillmore, 1957; and Hemp-

hill, 1958a). Certain instruments permit only the measurement of altitude differences, others permit only the orthographic positioning of geologic data, but many instruments are used for both measuring and plotting. Most measuring and plotting devices are designed to accommodate standard 9- by 9-inch photographs; enlarged photographs can be used with only a few instruments, such as the overhead projector, in transferring data to a base sheet.

MEASURING DEVICES FOR USE WITH PAPER PRINTS

One of the most commonly used and widely available types of instrument for determining altitudes from paper prints of aerial photographs is the stereometer or parallax bar. Several varieties of stereometers are available for use with either the lens or mirror-type stereoscope (see fig. 10); they consist of two small plates, usually of glass or plastic, that have inscribed dots, or other targets, that can be centered over conjugate image points in a stereoscopic pair of photographs. The plates are attached to a supporting bar along which they may be separated horizontally. The supporting bar generally has graduated readings in millimeters or inches and a slow-motion adjustment drum that permits readings of hundredths of millimeters or thousandths of inches. All stereometers are based on the "floating-dot" principle, where two target dots, one seen with each eye, are fused stereoscopically into a single dot that appears to float in space within the stereoscopic model. The apparent height of the single fused dot, used as a reference mark in determining altitude differences, is related to the horizontal separation of the individual dots being viewed. Thus by measuring the horizontal separation between individual dots when the fused dot in the stereoscopic model is placed at the top of an object (such as a hill or cliff) whose height is to be determined, and subtracting from it the measurement of the horizontal separation between individual dots when the fused dot is placed at the bottom of that object, a measure of the height, called differential parallax, is obtained. Differential parallax is converted to feet by simple mathematical calculations (see p. 53). Stereometers are thus merely devices that permit reliable measurement of differences of horizontal distances between two or more pairs of conjugate image points as seen on two photographs that form a stereoscopic pair.

Parallax ladders also may be used for determining differences in altitudes from aerial photographs. Like the stereometer, the parallax ladder is based on the floating-dot or floating-line principle. The instrument may consist of two diverging rows of dots on plastic or glass arms; thus, a series of pairs of dots exist with

different horizontal separations, and this in turn results in several floating dots all at different altitudes within the stereoscopic model (see fig. 12). Or the instrument may consist of two diverging lines with intercepts of specific horizontal separations ticked off; thus a single plunging line would be seen in stereoscopic view. The instrument, oriented at right angles to the flight line, is used by sliding it over the stereoscopic model until a pair of dots or line intercepts—seen stereoscopically as a single dot or cross in space—appears to fall on the base of the object whose height is to be determined. A reading of the horizontal separation of the two dots or intercepts is then made. The parallax ladder is moved until a different pair of dots or intercepts—also seen stereoscopically as a single dot or cross in space—appears to fall on the top of the object whose height is to be determined. Again a reading of the horizontal separation of dots or intercepts is made. The difference in readings obtained is then used in a simple formula to determine the difference in altitude of the two points (see p. 53). A direct-reading parallax ladder that eliminates the need for most of the mathematical computation has also been devised. The differences in horizontal separation of pairs of dots has been calculated by the manufacturer in terms of heights in feet for different flying heights and photobases, and this permits a direct reading of relative altitudes within the stereoscopic model.

Also for use with paper prints is a stereo slope meter, designed primarily for determining degrees or percentage of slope. The instrument consists of two transparent disks each scribed with eccentric circles of specific diameters (fig. 11). These disks are mounted in a frame so as to be movable horizontally in a fashion similar to the dots of the stereometer. In stereoscopic view the two sets of eccentric circles appear as a cone that is divided into several zones. By proper horizontal spacing of the two disks, the resulting cone seen stereoscopically can be raised or lowered so that some two circles will rest on the slope or grade to be determined. By appropriate simple calculations the slope can be determined. Center dots present on each of the transparent disks also permit relative altitudes to be determined just as with a stereometer.

PLOTTING DEVICES FOR USE WITH PAPER PRINTS

Instruments have been designed specifically for plotting information from paper prints to base maps or control sheets. An instrument widely employed in the past is the sketchmaster (fig. 13), which uses the camera-lucida principle in transferring data from the photographs to the base sheet. The sketchmaster

allows the operator to view a single photograph image superposed on the base map. Adjustments for scale changes in the perspective photograph permit coincidence or near coincidence of photograph control points and base-map control points. Geologic detail is sketched directly on the base map. This instrument can be adjusted to remove small amounts of tilt inherent in some vertical photographs, but like any direct-reflecting projector, large amounts of radial displacement due to relief cannot be effectively removed.

The radial planimetric plotter has been devised especially for transferring photographic detail to a base map or control sheet. Unlike the sketchmaster, this instrument is designed to eliminate displacement due to relief. The plotter consists of a mirror stereoscope mounted above two photograph tables (fig. 14). A transparent plastic arm with a centrally scribed line extends from and pivots around the center of each table. These arms are linked to a pantograph attachment. Because the plastic arms radiate from different centers they cross each other in stereoscopic view to form the so-called plotting cross.

In operating the radial planimetric plotter a pair of vertical photographs is oriented on the photograph tables for proper stereoscopic viewing, and control points on the photographs are oriented to control points on the base manuscript by means of the radial arms and pantograph. Movement of the pantograph attachment moves the plotting cross over the stereoscopic model and permits tracing of photograph detail on the base manuscript. Inasmuch as the radial arms that intersect a terrain feature on each photograph represent azimuth lines from known points on the base manuscript, the intersection of these two arms will represent the true map position of that feature, just as will the intersection of two azimuth lines shot from different instrument stations in the field. Thus the relief displacement of a feature on a photograph is effectively removed; this is one of the chief advantages in using the radial planimetric plotter. However, the radial lines do not intersect along the principal line—or flight-line direction—between photographs, and the photograph tables must be shifted to their alternate centers before the central area of stereoscopic model can be delineated. Because the photograph tables are mounted in a horizontal position, the instrument does not permit removal of tilt that may be present in the photographs, but tilt is usually small in present-day photography and generally does not cause significant errors in horizontal positioning of geologic data.

The multiscope is a combination of mirror stereoscope and camera lucida that has received limited use

COMBINED MEASURING AND PLOTTING INSTRUMENT FOR USE WITH PAPER PRINTS

in plotting geologic data from photographs to base maps or control sheets. Photographs are mounted on movable photograph plates that permit small adjustments for tilt. The viewing assembly is constructed to allow the insertion of one or two half-silvered mirrors in the eyepiece, so that in operation either the image of a single photograph or the stereoscopic model may be superposed optically on the map or control base. Although the stereoscopic model may be seen at all times, use of only one half-silvered mirror permits the eye to see only the image of one photograph superposed on the map base; the resulting plot is similar to that from the sketchmaster—or reflecting projector—no errors due to relief displacement are removed. If, however, two half-silvered mirrors are used, appropriate manipulations permit true orthographic plotting of detail from the stereoscopic model. Scale adjustments between photographs and map base are made by interchanging special lenses in the viewing assembly together with changing manually the distance of the viewing assembly above the map base. The instrument is said to permit measurement of altitudes when coupled rotary prisms are inserted under the half-silvered mirrors, or when a device similar to the multiplex tracing table is placed in the field of stereoscopic view (Spurr and Brown, 1945, p. 177).

MEASURING AND PLOTTING DEVICES FOR USE WITH PAPER PRINTS

Some instruments have been designed both for measuring altitudes and for plotting data from paper prints of aerial photographs. These instruments are commonly termed "paper-print plotters" and include the KEK plotter, the Mahan plotter, and the stereotape.

The KEK plotter consists of a stereoscope, two photograph tables, floating-dot assembly, and drawing attachment. The plotting cross of the radial planimetric plotter is replaced in the KEK plotter by the fused dot floating in space. By raising or lowering the photograph plates the fused dot is positioned on the ground in the stereoscopic model. Vertical motion of the photograph plates is linked to a drum scale on which relative altitudes can be read directly in feet. Movement of the pantograph drawing attachment allows geologic detail to be sketched directly on the map base, but during this sketching the fused dot must be held on the ground in the stereoscopic model by simultaneous vertical movement of the photograph plates. The photograph plates may be tilted to make an approximate correction for tilt that may be inherent in the photography. Because the floating-dot assembly lies above and is physically separated from the photograph tables, small amounts of extraneous paral-

lax and significant amounts of horizontal shift in the map position of a point may result by moving one's head in viewing the stereoscopic model.

The Mahan plotter is generally similar in principle to the KEK plotter but differs slightly in operation. The floating dot is positioned on the ground in the stereoscopic model by vertical motion of the disks on which the dots are scribed, whereas in the KEK plotter the position of the disks containing the scribed dots is fixed and the photograph plates are moved vertically in order to position the floating dot at a particular level in the stereoscopic model. The stereoscope of the Mahan plotter is adjustable, which permits very nearly the recovery of the perspective from photography ranging in focal length from about 8.25 to 12 inches. As with the KEK plotter, a shift of the viewer's head when viewing the model may cause horizontal positioning errors and the presence of small amounts of extraneous parallax. The stereoscopic model of the KEK and Mahan plotters may be effectively leveled, in absence of vertical control, by visual reference to certain physiographic features of the terrain (see p. 55).

A somewhat different paper-print plotter is the stereotape. The instrument consists of a stereoscope with binoculars of $\times 4$ magnification mounted over a photoholding assembly that contains a parallax bar and attachments for pantograph hookup, as well as a mechanism, when vertical control is available, for effectively leveling tilted models, for correcting errors of horizontal position, and for orthographic plotting of geologic data (fig. 15). The stereotape is an elaborate instrument that corrects for tilt by mechanical linkages within the photoholding assembly. No physical tilting of the photoholders takes place and thus the instrument differs significantly from the KEK and Mahan plotters. In addition, the targets of the stereometer attachment for altitude determinations are in contact with the paper prints, and no extraneous parallax can be introduced by movement of the operator's viewing position. In the absence of vertical control, which permits tilt correction through mechanical linkages, the stereotape as a measuring device must be used as a simple parallax bar.

MEASURING AND PLOTTING DEVICES FOR USE WITH GLASS-PLATE DIAPOSITIVES

The Kelsh plotter, multiplex, and ER-55 plotter, all of which require glass-plate diapositives, are used in the United States both to measure quantitative geologic data and to plot geologic detail to base maps or control sheets (figs. 16-18). These double-projection precision-plotting instruments are designed to accom-

FIGURE 16.—Multiplex.

FIGURE 17.—ER-55 plotter.

FIGURE 18.—Kelsh plotter.

COMBINED MEASURING AND PLOTTING INSTRUMENTS FOR USE WITH GLASS-PLATE
DIAPOSITIVES

moderate photography of specific focal lengths, usually 6 or 8.25 inches. All utilize the anaglyph principle of projection of light of complementary colors, red and blue-green, through glass-plate diapositives to create the third dimension. The stereoscopic model is viewed through glasses of the same color as the filters used in the light-source projectors. Because double-projection, or anaglyphic-type, stereoplotting instruments simulate in miniature the spatial relations of the camera stations at the time the photographs were taken, all features of the terrain are optically re-created in the stereoscopic model in essentially true relation with respect to the measuring mark or floating dot. Where sufficient vertical control is available any tilt inherent in the photography can be removed so that accurate measurements of altitudes can be made and true orthographic positioning of detail obtained. Without vertical control the stereoscopic model of many terrains commonly can be leveled within 1° of the horizontal datum by visual reference to certain physiographic characteristics of the terrain (see p. 55); under these conditions approximate orthographic positioning may be obtained, but significant errors in vertical measurements may result (see p. 69-75).

The stereoscopic model is usually viewed on a small white-surfaced table called a platen, which may be raised and lowered so that an illuminated floating dot in its center is kept in contact with the surface of the ground, as seen in stereoscopic view. Vertical motion of the platen is transmitted to a scale reading in millimeters of vertical measurement, or, on some instruments, to a scale that converts readings directly to heights in meters or feet. Geologic features are traced orthographically on the base map by a pencil located directly beneath the illuminated dot on the platen, or by a reduction pantograph attached to the tracing table. Interpretation, measuring, and plotting can be carried out in one continuous operation.

The Kelsh plotter is designed to accommodate glass-plate diapositives the same scale as the original photography. For many geologic problems film positives may be substituted for the more expensive glass-plate diapositives. The scale of the projected stereoscopic model is usually about 5 times that of the original photography. Only that part of the stereoscopic model appearing on the platen is illuminated; this results in a concentration of light and a brightly illuminated model but prevents viewing of the entire model at one time. Because the glass-plate diapositives are the same scale as the original photography the resolution of the stereoscopic image is excellent.

The multiplex uses glass-plate diapositives on which the original 9- by 9-inch negative is reduced about

5 times. The small diapositive image is then enlarged approximately 12 times in projection of the stereoscopic model. The projected stereoscopic model is about 2.5 times the original photography scale. As a result of the large amount of reduction of the original photograph negative, some of the photographic detail is lost and fine details of terrain, important in geologic interpretation, may not be visible. In multiplex projection the entire model area is illuminated, and if the terrain being viewed has only low or moderate relief the stereoscopic model may be observed in its entirety by substituting a large white surface for the platen. This overall view of the stereoscopic model is often of considerable use in geologic interpretation, because of the association of geologic features that can be seen at one time. The overall view is generally accomplished by projecting the stereoscopic model to the multiplex table slate; no plotting or measuring can be done when the model is viewed on this surface.

The ER-55 plotter uses glass-plate diapositives on which the original 9- by 9-inch negative is reduced about 2.8 times; this amount of reduction does not seriously affect image resolution. The projected stereoscopic model is about 3.5 or 5 times the scale of the original photographs, depending on the projector model. Ellipsoidal reflector-type projectors result in a brightly illuminated model in which terrain detail has a high degree of resolution. Like the multiplex, the ER-55 plotter permits viewing the entire stereoscopic model at one time. In addition to accommodating vertical photography the ER-55 projectors are adaptable to twin low-oblique photography taken with the camera axis inclined 20° from the vertical position.

Geologic study of stereoscopic models in double-projection plotters has numerous advantages over the study of paper prints. The ability to interpret, measure, and plot in one continuous operation has already been cited. In addition, the geologist works with an enlarged stereoscopic model that ranges from about 2.5 times to 5 times the original photography scale, depending on the instrument used; thus small-scale photography commonly may be used. A higher degree of image resolution is maintained on glass diapositives than on paper prints, and results in more detail that can be observed in the double-projection stereoscopic models, except for the multiplex, in which some resolution needed in qualitative and quantitative interpretation is lost in the projected model. Because all features of the terrain are optically re-created in essentially true relation, reliable measurements for structure contouring, for drawing isopach lines, for computing strikes and dips, and for determining fault displacements can be obtained for many areas with stereo-

scopic plotters; measurements can be made rapidly and hence economically (see Pillmore, 1957).

OTHER INSTRUMENTS

Other photogrammetric instruments such as the stereoplanigraph and autograph permit precise measurements from aerial photographs, but these heavy plotters are generally unavailable to the geologist. Beside permitting precision of measurement, these instruments are designed to accommodate different sizes of diapositives and photography taken with different focal-length lenses.

Certain modifications or additions to existing instruments have been made specifically for geologic purposes; and some new instruments, described below, have been designed expressly for geologic study.

EXAGGERATED-PROFILE PLOTTER

The exaggerated-profile plotter is a device attached to the tracing table of double-projection plotters, such as the Kelsh, multiplex, and ER-55 plotters, for drawing terrain profiles. As the tracing table is moved along the line of profile and as the platen of the tracing table is moved vertically a pencil attachment records the profile on a vertical tracing board. Profiles exaggerated as much as 5 times may be plotted. An arm on the tracing table slides in a groove along the base of the tracing board so that a selected cross-section direction is maintained. Two models of the exaggerated-profile plotter have been developed. One is based on the lever and fulcrum principle (fig. 19); the other is based on the pantograph principle (fig. 20). The exaggerated-profile plotter was first developed to aid in solving a specific geologic problem in correlating thin and closely spaced intraformational sandstone beds in rocks of Cretaceous and Jurassic age in Wyoming (Pillmore, C. L., oral communication, 1958). The plotter may be very useful also in quantitative geomorphic studies or in studies involving the qualitative correlation of shape characteristics of terrain.

INTERVAL-MEASURING DEVICE

A floating-dot instrument that permits the maintenance of a desired vertical interval between two floating dots in a stereoscopic model from paper prints, as well as serving as a conventional stereometer, also has been developed in the course of photogeologic study (Hackman, R. J., oral communication, 1959). Two floating dots, representing different altitudes in the stereoscopic model, may be useful for example in positioning an obscured formation contact when other contacts are readily observed and formation thicknesses are known. The instrument consists of two transparent circular disks mounted on a frame with two worm

screws, one of which permits separation of the disks in the x direction, and the other of which permits both disks to be rotated equally but in opposite directions (see fig. 21). A series of dots, evenly spaced, are arranged in a straight line so as to pass through the center of each disk. One dot coincides with the center of each disk and can be moved only in the x direction, as in most stereometer-type instruments. The other dots may also be moved in the plane of the disk by rotating the disk, thus providing a parallax ladder as seen stereoscopically. By proper adjustment a pair of dots, one on each disk, can be separated by rotation of the disks to provide a direct-reading parallax ladder, or the dot separation may be referred to millimeters of parallax and differences in altitude calculated in the usual manner (see p. 53). The center dots of each disk can be floated in the stereoscopic model at a desired point and the distance above or below this point measured merely by rotation of the disks. Scales graduated to record hundredths of millimeters of parallax permit readings of separation of the center dots of the disks as well as reading of total x parallax resulting from rotation or x motion of the disks.

UNIVERSAL TRACING TABLE

Some research in development of instruments carried out to date has centered around the modification of existing instruments. Important in this group is the universal tracing table (fig. 22), which is a multiplex tracing table that has been modified in design by R. H. Morris and C. L. Pillmore of the Geologic Survey. It is used for direct measurement of inclined distances, such as stratigraphic thickness of dipping beds, in stereoscopic models from double-projection plotters. The platen and underlying assembly can be tilted as much as 45° . A separate worm-screw drive on the tilted assembly distinct from the conventional worm-screw drive for vertical movement, permits movement of the platen in an inclined direction perpendicular to the surface of the platen. A scale on this auxiliary worm-screw-drive assembly permits the reading of measured intervals in hundredths of millimeters; conversion to feet is made in the usual manner for double-projection stereoscopic models (see p. 54-55). A series of holes drilled through the platen to the underlying light source provides a plane of floating dots in the stereoscopic model.

MEASUREMENT

PRINCIPLES OF VERTICAL MEASUREMENT

Vertical measurements of altitude differences provide by far the greatest amount of quantitative information in geologic interpretation from aerial photographs. Differences of altitudes are generally deter-

FIGURE 19.—Lever and fulcrum type of exaggerated-profile plotter.

INSTRUMENTS DESIGNED OR MODIFIED FOR GEOLOGIC USE

mined from overlapping aerial photographs, although they may under special circumstances be determined from a single photograph. When overlapping prints are used, the altitude difference between any two points is determined by measuring the horizontal linear parallax difference between the two points and relating it to appropriate geometry of the stereoscopic model. Altitude determinations from glass plates in double-projection plotters require the measurement of actual vertical distances within the stereoscopic model. In the uncommon circumstance when a single photograph may be used, altitudes are determined by measuring relief displacement and relating it to appropriate geometry of the aerial photograph.

DETERMINATION OF ALTITUDE DIFFERENCES BY THE PARALLAX METHOD

When an object is viewed or photographed from two different positions, as on two overlapping vertical aerial photographs, an apparent shift in the position of that object takes place, which is known as paral-

lactic displacement. On overlapping aerial photographs this is a measurable linear distance that is directly related to the height of the object. In photogrammetric terms parallax of an image point appearing on two overlapping photographs is called absolute stereoscopic parallax and is represented by the algebraic difference, parallel to the flight line, of the distances of the conjugate image points from their respective principal points (see fig. 23). The difference in absolute stereoscopic parallaxes between two different image points is a measure of the distance one point is above the other. On overlapping paper prints the parallax difference may be measured reliably by using a stereometer-type instrument, based on the floating-dot principle; parallax difference may also be measured with a ruler, although this procedure is rarely used because of inaccuracy of measurement.

In double-projection stereoplotters (Kelsh, multiplex, and ER-55 plotters) an actual vertical measurement of altitude difference is made within

FIGURE 23.—Diagram showing relation between absolute stereoscopic parallaxes and horizontal distances actually measured with stereometer-type instruments in determining differences in altitude from paper prints.

Let images $P_1'-P_2'$ and P_1-P_2 represent the photographic expression of a pole on the left and right photographs of a stereoscopic pair. The absolute stereoscopic parallax of the base of the pole is $x - (-x') = (x + x')$. The absolute stereoscopic parallax of the top of the pole is $y - (-y') = (y + y')$. (Distances measured to the right of the principal point are positive, to the left, negative). The parallax difference between the top and bottom of the pole then is $(y + y') - (x + x')$.

From the figure:

$$\begin{aligned} y + y' + B &= x + x' + A \\ y + y' - x - x' &= A - B \\ (y + y') - (x + x') &= A - B. \end{aligned}$$

Thus the difference in absolute stereoscopic parallaxes is equal to $A - B$. The distances A and B are the actual distances measured with stereometer-type instruments, generally in hundredths of millimeters, in determining altitude differences from paper prints.

the stereoscopic model; the linear parallax recorded on the photograph is translated into a vertical distance as a result of angular parallax in the viewing arrangement. Figures 23 and 24 show diagrammatically the distances that are actually measured when stereometer-type instruments and double-projection instruments are used respectively in altitude determinations.

USE OF STEREOMETER-TYPE INSTRUMENTS

When paper prints of aerial photographs are used in conjunction with a stereometer-type instrument and a stereoscope, two linear horizontal distances must be measured to obtain the parallax difference between two different image points. These distances are simply A and B as shown on figure 23. They can be measured with a finely graduated ruler but more commonly a

FIGURE 24.—Diagram showing relation between absolute stereoscopic parallaxes and vertical distance measured with double-projection type instruments in determining differences in altitude from glass plates.

The absolute stereoscopic parallaxes of the top and bottom of a pole represented on the left photograph by P_1 - P_2 and on the right photograph by P_1' - P_2' are $(y + y')$ and $(x + x')$, as in figure 23, and differential parallax between the top and bottom of the pole is $(y + y') - (x + x')$ or $A - B$. With double-projection instruments the vertical distance CD is actually measured, rather than the horizontal distances that are measured on

paper prints. The distance CD , measured generally in tenths of millimeters, is converted to feet by multiplying by the K factor, which represents the number of feet on the ground per 0.1 millimeter in the stereoscopic model. Points C and D represent the intersections of those light rays that pass through the top and bottom of the pole respectively.

stereometer-type instrument or parallax bar is used because it permits more consistent readings of smaller increments of length than a ruler. Stereometers are generally constructed with a principal scale graduated in millimeters and a subordinate drum scale calibrated in hundredths of millimeters for recording parallax measurements; a few instruments are designed to record in inches.

To make parallax measurements from aerial photographs it is first necessary to orient the photographs properly for stereoscopic viewing. This is accomplished by aligning the photograph centers and conjugate centers along a straight line—the equivalent of the flight-line direction—and separating the photographs for comfortable viewing (fig. 25). Photograph centers are located by marking the intersections of lines drawn between fiducial marks at the opposite sides of each print. Each center is then transferred stereoscopically to the other photograph of the stereo-

scopic pair and its conjugate image point marked. Parallax measurements are then made in the so-called x direction, parallel to the flight line. Measurement is accomplished by adjusting the separation of the dots of the parallax bar until a single fused dot, seen stereoscopically, appears to rest on the ground at the first point selected. The instrument reading is recorded and the procedure is repeated for the second point selected. The difference in readings is the parallax difference between the two points. In making parallax measurements the fused dot will be seen readily when it floats above the apparent ground surface of the stereoscopic model but will appear to split into its two component dots as it is lowered below the ground surface. If the fused dot, as it is being lowered, appears to split at some point just above the ground surface, a slight change in the separation of the photographs may be necessary to permit simultaneous viewing of the floating dot and the stereoscopic model.

FIGURE 25.—Sketch showing correct orientation of photographs for stereoscopic viewing.

To obtain the height of an object or difference in altitude between two points the difference in parallax must be related to the geometry of the stereoscopic model. For measuring heights from paper prints this relation is best expressed by a formula which, in its simplest terms, is

$$h = \frac{H}{b} \cdot \Delta p \quad (1)$$

where h = height of the object, in feet, or difference in altitude being determined;

H = height of airplane, in feet, above mean terrain (determined from specifications of photographic mission or relation $H = f/S$, see below);

b = photobase (commonly determined by averaging the distances between the center and conjugate center of each photograph of the stereoscopic pair); units of measure may be millimeters or inches but must be the same as Δp ;

and Δp = parallax difference, in millimeters or inches, as determined with stereometer-type instrument (distance $A-B$ of figure 23).

It will be noted that as H increases, the measure of Δp for any given vertical interval will decrease; however, the absolute value for any one unit of Δp will increase correspondingly. On the other hand, if focal length is increased and flying height remains constant the measure of Δp for a given vertical interval will increase but the absolute value for any one unit of Δp will decrease correspondingly.

The above formula (1) may be used without any appreciable error if relief in an area is low; Δp will be small. If relief in an area is high one of the following two formulas, (2) or (3), should be used:

$$h = \frac{H'}{ab + \Delta p} \cdot \Delta p \quad (2)$$

where h = height of the object, in feet, or difference in altitude being determined;

H' = height of airplane, in feet, above the lower of the two points whose parallax difference has been measured;

ab = photobase adjusted to the lower of the two points whose parallax difference has been measured (commonly determined by measuring the distance between photograph centers— $O-O'$ of fig. 23—and subtracting from it the distance between conjugate image points at the lower altitude—distance A of fig. 23); units of measure may be millimeters or inches but must be the same as Δp ;

and Δp = parallax difference, in millimeters or inches, measured with stereometer-type instrument (distance $A-B$ of figure 23);

$$\text{or} \quad h = \frac{H'}{ab - \Delta p} \cdot \Delta p \quad (3)$$

where h = height of the object, in feet, or difference in altitude being determined;

H' = height of airplane, in feet, above the upper of the two points whose parallax difference has been measured;

ab = photobase adjusted to the upper of the two points whose parallax difference has been measured (commonly determined by measuring the distance between photograph centers— $O-O'$ of fig. 23—and subtracting from it the distance between conjugate image points at the upper altitude—distance B of fig. 23); units of measure may be millimeters or inches but must be the same as Δp ;

and Δp = parallax difference, in millimeters or inches, measured with stereometer-type instrument (distance $A-B$ of figure 23).

Formula (2) is used when H' and ab are determined by referring to the lower of the two points whose altitude difference is desired, as in measuring upward from the base to the top of a cliff. Formula (3) is used when H' and ab are referred to the upper point, as in measuring downward from the top to the bottom of a cliff. Most commonly the lower of two points is selected as the reference point and measurements are made from that point to some higher point in the stereoscopic model; thus formula (2) is more widely used than formula (3).

Parallax differences generally can be read within small tolerances (see p. 73), and errors in computing differences in altitude result mainly in the determination of flying height and photobase, assuming photographs have little or no tilt. It is therefore generally desirable to determine flying height (H') and adjusted photobase (ab) carefully because a given percentage error in one of them may cause a similar percentage error in the computation of altitude difference. In addition, failure to use formula (2) or (3) when parallax difference (Δp) is large will also cause a considerable error in the final result even though the adjusted photobase (ab) has been carefully determined.

For calculation of absolute heights as is necessary, for example, in determining stratigraphic thickness or displacement on faults, the factor H' may be determined from a base map of known scale or from other control using the relation $H' = f/S$. If the altitude difference between some two points, A and B , is desired

and if neither A nor B falls in a convenient map position for scaling a distance and determining H' for one of them, it may be necessary to make parallax measurements with respect to some selected third point, C , for which the flying height (H') can be readily calculated.

Where altitudes are to be used for computing angles of dip it is not necessary to know the absolute height of H' ; the tangent relation of angles

$$\text{Tan angle of dip} = \frac{\text{vertical distance}}{\text{horizontal distance}} \quad (4)$$

involves only relative horizontal distances and relative differences of altitudes, and thus any value may be assumed for H' when measuring parallax difference and determining the scale of the photograph to be used in computing dips. In photogrammetric terms this relation may be expressed as

$$\text{Tan angle of dip} = \frac{\text{flying height (feet)} \times \text{parallax difference}}{\text{horizontal distance on ground (feet)} \times \text{adjusted photobase}} \quad (5)$$

$$\text{or Tan angle of dip} = \frac{H' \cdot \Delta p}{d \cdot (ab \pm \Delta p)} \quad (6)$$

Since

$$\frac{\text{flying height (feet)}}{\text{horizontal distance on ground (feet)}}$$

is also equal to

$$\frac{\text{focal length (inches)}}{\text{horizontal distance on photograph (inches)}}$$

the following formula may also be used to calculate angles of dip when flying height, H' , is not known or cannot be determined:

$$\text{Tan angle of dip} = \frac{\text{focal length} \times \text{parallax difference}}{\text{horizontal distance on photograph} \times \text{adjusted photobase}} \quad (7)$$

The tangent of dip, in photogrammetric terms, has been described in more detail by Desjardins (1943b, p. 1536-1538) and Elliott (1952, p. 8). When angles of dip are determined from enlarged photographs and formula (7) is used, the effect of photographic enlargement on focal length must be considered; effective focal length is increased in direct proportion to the amount of photographic enlargement (see p. 4).

Hemphill (1958a, p. 43) has devised a chart that shows the number of feet represented by each millimeter of parallax change as H' and $(ab + \Delta p)$ of formula (2) vary. The factor determined from the chart is then multiplied by Δp to arrive at h , in feet, pro-

vided formula (2) is used. A simple circular photogrammetric computer has also been designed that permits easy computation of the number of feet represented by each millimeter or hundredth millimeter of parallax as flying height and photobase vary. In addition, the computer allows multiplication of this factor by the parallax change to give altitude differences in feet. The number of feet represented by each hundredth millimeter of parallax measured on paper prints may also be determined from the ratio

$$\frac{\text{Flying height (feet)}}{\text{Photobase (millimeters)} \times 100}$$

This relation is further discussed on page 73.

Need for correct orientation of photographs.—Misorientation of a stereopair of photographs can be considered from the standpoint of rotation around the center of one or both of the photographs. This rotation results in misalignment of the stereopair and flight line. Parallax differences are not then measured in the true x direction, or flight-line direction, but at a slight angle to it; an error in the adjusted photobase also results. The measurement of parallax difference is not normally significantly affected but the adjusted photobase on a stereopair misoriented by a few degrees, even though the human eyes can tolerate a certain amount of error and yet see a well-defined stereoscopic image, may be in error by as much as 5 to 10 percent. This will cause a similar error in differences in altitudes determined by the parallax method when paper prints are used.

USE OF DOUBLE-PROJECTION INSTRUMENTS

When double-projection instruments are used to determine altitude difference between two points, only one distance need be measured. This is a vertical distance within the stereoscopic model that results from the translation of linear parallax recorded on the glass-plate diapositives to angular parallax in the viewing arrangement (fig. 24). The vertical position of intersecting light rays to the lower point to be measured is determined by placing the floating dot on the apparent ground in the stereoscopic model and recording the instrument reading. The vertical position of the upper point is recorded in a similar manner. The difference in readings is a measure of the parallactic displacement and is related to the difference in altitude of the two points. With double-projection instruments measurements are normally made in increments of tenths of millimeters, although some instruments are so designed that selection of proper gear trains permits readings to be converted directly to heights in meters or feet.

In stereoscopic models formed in double-projection instruments the vertical scale remains constant with

respect to the horizontal scale and a simple multiplication factor—called the *K* factor—for relating increments of vertical measurement to absolute feet can be determined by converting the standard fractional scale (representative fraction) of the model to feet per unit of vertical measurement, that is, per 0.1 millimeter. This is most rapidly accomplished using the formula

$$K = \frac{\text{model scale denominator}}{3,048 \text{ (number of tenths of millimeters in 1 foot)}}$$

Thus a stereoscopic model with a scale of 1:4,000 would have a *K* factor of 4,000/3,048 or 1.31 feet per 0.1 millimeter of vertical measurement. Increments of vertical measurement are merely multiplied by the appropriate *K* factor to obtain differences in altitude in feet. A constant factor for converting increments of vertical measurement to feet is appropriate because the horizontal and vertical scales are equal and constant throughout the stereoscopic model, but when paper prints are used, the horizontal scale is not constant throughout the model and hence different multiplication factors must be determined for different levels in the model.

Because the horizontal and vertical scales in stereoscopic models from double-projection instruments are equal and constant throughout the model, inclined distances, such as stratigraphic thicknesses of dipping beds, may also be measured. A special device for measuring distances in inclined directions was developed by R. H. Morris and C. L. Pillmore of the Geological Survey; it consists of a multiplex tracing table modified so that the platen, platen socket, and light source can be tilted as a unit (fig. 22). An additional worm-screw drive, separate from the conventional worm-screw drive, allows the platen to move in an inclined direction perpendicular to the surface of the platen. The resulting measured distance within the model is converted to feet in the usual manner, and a measure of the inclined distance is obtained.

TILT

Tilt in present-day vertical photography is generally small—under good flying and photographic conditions 50 percent of the photographs taken for domestic mapping are reported to be tilted less than 1° and 90 percent tilted less than 2° (see Tewinkel, 1952, p. 319). But tilt may be significant in the photogrammetric calculation of many geologic measurements, and care must therefore be exercised in determining altitudes from parallax measurements. The significance of tilt on vertical measurements used in geologic interpretation depends in large part on the geologic problem. Where vertical measurements must be referred to a

horizontal datum, as in structure contouring, tilt may cause significant errors, but where relative vertical measurements between pairs of points are desired, as in constructing isopach lines, tilt may have relatively little effect especially where points of any one pair are separated by only a small horizontal distance (see p. 73). If only simple stereometers are available for parallax determinations it may be necessary to entirely discard some photograph prints unless (a) vertical control is available and the geologist carries out the tedious task of constructing a correction graph (Desjardins, 1950, p. 2304–2305; McNeil, 1952, p. 610–615; and Visser, 1954, p. 849–853), or (b) points of measurement are selected so that the effect of tilt will be minimized (Hemphill, 1958a, p. 46–47, 49). It is also possible to partially correct for tilt locally on planar orientations, such as the strike and dip of beds, by stereographic projection and appropriate rotations in stereographic constructions.

If photogrammetric instruments are available that allow photographs to be tilted, it is generally possible to eliminate any large amount of tilt (greater than 1°) by careful inspection of physiographic features of the stereoscopic model, thereby permitting reliable parallax measurements to be made even though vertical control is not available for leveling the model. For example, lakes or other standing bodies of water may appear tilted, or certain streams or stream meanders may appear to flow uphill (fig. 109). Tilt is also often detected by observing that headwater tributaries in subdued divide areas where gradients are very low appear to flow uphill. Adjustment of the instrument so that the lakes appear flat and streams have a normal gradient will minimize tilt, and parallax measurements can then be made.

For certain sensitive measurements, such as measurement of low stream gradients or measurements used to determine the strike of low-dipping beds, it is essential that vertical control for leveling models be available and that a precision plotting instrument, such as the Kelsh plotter, be used. Because a small amount of tilt may seriously affect the measure of stream gradient the economic advantage of photogrammetric techniques may be lost where the measure of gradients is the primary photogrammetric objective, inasmuch as a considerable amount of vertical control must be obtained by ground survey to level the stereoscopic models. However, for many geologic measurements, particularly where relative intervals are to be measured, ground control, although desirable, is not essential for making satisfactory parallax determinations, either from paper prints or glass-plate diapositives.

DETERMINATION OF ALTITUDE DIFFERENCES FROM A SINGLE PHOTOGRAPH

Under certain conditions altitude differences between two points may be determined by making appropriate measurements of radial displacement on a single photograph and substituting them in the formula

$$h = \frac{mH}{r}$$

where h = difference in altitude desired;

m = relief displacement of upper image point with respect to the lower image point;

H = height of airplane above lower image point;

and r = radial distance from principal point of photograph to lower image point.

The distance m and r must be measured in the same units. The height, h , will then be in terms of the units chosen for H .

This procedure is only applicable to vertical objects where the upper point is known to be directly above the lower point. Under these restricted conditions, the length of the image of an object, such as a tree, or a cliff face at right angles to a radial line from the principal point, is a measure of the relief displacement. The radial distance to the lower point can be easily measured, and the flying height can be obtained from the formula $H = f/S$ (see p. 53-54) when base maps are available, or from the specifications of the photographic mission. Thus, for example, if the radial displacement of a cliff is 0.03 inch, the flying height of the airplane 10,000 feet, and the lower point is 3 inches from the photograph center, the height of the cliff will be

$$h = \frac{0.03 \times 10,000}{3.0}$$

$$h = 100 \text{ feet.}$$

Because relief displacement is generally small, a small error in measuring such a distance on a single photograph will result in a relatively large error in the height of the object, which further limits the usefulness of the formula for determining vertical intervals.

GEOLOGIC USES OF PARALLAX MEASUREMENTS

Parallax measurements always result in the determination of spot altitudes or vertical intervals when paper prints are used; and generally result in spot altitudes or vertical intervals when glass-plate diapositives are used in double-projection instruments, except when a special tracing table is used that permits measurement of inclined distances (fig. 22). These spot altitudes and differences in altitudes combined with horizontal distances determined from the stereoscopic model, or under some circumstances from

a single photograph, may be used to compile structure-contour maps and to determine dips of beds, thicknesses of beds, offsets on faults, gradients of streams, and related data.

Because of relief displacement, however, it may be necessary to correctly locate the relative horizontal positions of points, whose altitudes have been measured, before computing strikes and dips, determining stratigraphic thicknesses, or any other geologic measurements where dips are involved. Because tilt is usually negligible in present-day photography, horizontal positions of points generally may be plotted satisfactorily with any instrument that removes relief displacement, such as the radial planimetric plotter, paper-print plotters, and double-projection plotters even though the stereoscopic model cannot be leveled. Horizontal distances may then be scaled off. However, in the absence of plotters for locating the relative map positions of radially displaced points when measurements are made with parallax bar and paper prints, an overlay or similar procedure may be used to determine corrected horizontal distances, unless orthophotographs (see page 69) are available from which correct horizontal distances may be scaled.

The overlay procedure requires first laying out on transparent material a line equal in length to the adjusted photobase. The overlay is then placed over the right photograph of the stereoscopic pair so that the line drawn is coincident with the flight direction and its right end terminates at the photograph center. Radial lines are then drawn on the overlay from the photograph center through all points whose relative horizontal positions are to be determined. The procedure is repeated with the overlay positioned over the left photograph, again with the original line coincident with the flight direction and its left end terminating at the photograph center. The intersection of a pair of lines through the same image points is the corrected horizontal position for that point.

DETERMINING STRIKES AND DIPS

Where bedding surfaces coincide with topographic surfaces it is generally sufficient to measure the altitude difference between only two points, one directly down-dip from the other in calculating the amount of dip. The horizontal distance between these two points, together with the difference in altitude, gives the required information for determining the angle of dip from the trigonometric relation

$$\frac{\text{Vertical distance}}{\text{Horizontal distance}} = \text{tangent of angle dip.}$$

If relief in an area is low the horizontal distance may be scaled directly from a single photograph with-

out significant error in computing the dip, but where relief is moderate or high a correction for the relief displacement of the upper point with respect to the lower point generally should be made. In the unique circumstance where the strike is radial from a photograph center or where the surface on which the dip to be measured is at or near a photograph center, there is little or no relief displacement in the dip direction, and no correction in scaling the horizontal distance need be made. Hemphill (1958a, p. 53) suggested that the corrected horizontal distance between the upper and lower points should be at least 0.2 inch for computing dip angles. Where dips are greater than 50° , a longer horizontal distance is needed to determine the dip angle reliably, as the tangent increment per degree of dip is significantly greater for steep angles of dip than for low angles of dip.

The strike line generally can be determined readily by inspection of the stereoscopic model and noting two points of equal altitude on a bed. Where dips are low, however, tilt in the photographs will affect the direction of strike; the lower the dip, the greater the effect, generally, on the amount of shift in the azimuth of the strike line. Graphs may be constructed to show the effect of tilt on low-dipping beds. (See Hemphill, 1958a, p. 48.)

Where a bed crops out in a valley wall it will generally be necessary to determine the altitudes of three points on the bed. In areas of moderate or high relief corrections for relief displacement must be made before distances between these points can be determined; otherwise distances may be scaled directly from the single photograph. Determination of the strike direction and amount of dip are then made graphically or graphically and trigonometrically.

DETERMINING STRATIGRAPHIC THICKNESS

In areas where beds are horizontal or nearly horizontal the stratigraphic thickness may be determined directly by converting to feet the parallax difference between the top and the bottom of the bed. No correction is necessary for relief displacement. However, if beds are inclined, the angle of dip must first be determined; then corrections must be made for relief displacement and for the effect of dip on the stratigraphic thickness. The thickness may be calculated by simple trigonometry or by graphic solution (fig. 26).

Desjardins (1950, p. 2308-2309; 1951, p. 829-830) suggested that floating lines be employed with paper prints for determining stratigraphic thicknesses where beds do not dip more than 15° . In the "floating line" procedure, lines are drawn on transparent strips of

Stratigraphic thickness is determined from the formula

$$t = x + x' = \frac{h}{\cos \theta} + \frac{d}{\sin \theta}$$

where t = stratigraphic thickness;

h = difference in altitude between some point on the lower contact of the bed and some point, along a line at right angles to the strike line, at the upper contact of the bed; altitude h is determined from the parallax formula;

d = corrected horizontal distance between points at lower and upper contacts of the bed;

and θ = angle of dip.

material that are superposed over each of the photographs. When one line over one photograph is positioned parallel to a line over the second photograph, a single floating line will appear when viewed stereoscopically unless the lines are parallel to the flight direction. The line will float above or within the model and appear to be horizontal; its vertical position in the model will depend on the separation of the two individual lines in the flight direction. A series of lines will form a grid or reference plane (Smith, H. T. U., 1943a, p. 171; Desjardins, 1943a, p. 219; Hackman, 1957, p. 593). When any one pair of lines is divergent rather than parallel the floating line in the stereoscopic model will appear to plunge. By changing the horizontal separation of any two lines in the flight direction the floating line can be made to rise or fall in the model, just as with the floating dot of the parallax bar. When the floating-line procedure is used in measuring stratigraphic thicknesses, a line is first floated preferably in the bedding plane at the upper formational contact, and parallax measurements are then made at the lower formational contact and on the floating line at a position in space vertically above this point (see fig. 27). If beds are

horizontal or nearly horizontal the parallax difference will be approximately a measure of the stratigraphic thickness. If the beds dip, the stratigraphic thickness will bear a cosine relation to the dip angle and parallax measurement (see fig. 27).

Where dips are steep it may be desirable to measure a horizontal distance along a line at right angles to the strike direction between two formation contacts and relate this distance and dip angle to stratigraphic thickness. Points must be chosen at approximately the same altitude in the stereoscopic model (fig. 28).

ISOPACH MAPPING

The use of aerial photographs in studies of certain areas in the Colorado Plateau of Western United States has included the photogrammetric compilation of isopach maps that show local thickenings of certain formations in which uranium minerals are likely to occur. These thickenings of formations are channel-fill deposits in stream channels that were cut in the underlying formation. Uranium minerals are locally concentrated in these deposits. In the Monument Valley area of southern Utah it has been demonstrated that isopach lines, indicating the trends and thicknesses of different channel-fill deposits, could be drawn

FIGURE 27.—Diagram of gently dipping beds showing relation of stratigraphic thickness to differential parallax determined by floating-line method.

Stratigraphic thickness is found from the formula

$$t = \frac{h}{\cos \theta}$$

where t = stratigraphic thickness;

h = difference in altitude between bottom of bed and point on floating line vertically above, as determined from the parallax formula;

and θ = angle equivalent to angle of dip.

on the basis of measurements made on vertical aerial photographs. In this area uranium minerals are present in channel-fill deposits at the base of the Shinarump member of the Chinle formation of Triassic age. However, because the top of the Shinarump member is eroded away in many areas, or because it is gradational with the overlying member of the Chinle formation, a stratigraphic unit below the Shinarump member was chosen as the unit for which isopach lines were drawn. A thinning of this underlying unit then was interpreted to indicate a thickening of, or channel deposits of, the overlying Shinarump member. The unit selected for isopach measurements, the Moenkopi formation, is expressed on aerial photographs as a dark-toned slope-forming unit that contrasts markedly with the light-toned cliff-forming units of both the underlying De Chelly sandstone member of the Cutler formation and the overlying Shinarump member of the Chinle formation (fig. 44).

A series of altitude measurements was then made along the contact of the Moenkopi and Shinarump formations from aerial photographs by means of the Kelsh plotter, and the locations of these measurements were plotted on a base sheet. Similarly, a series of altitude measurements was made along the contact of the De Chelly and Moenkopi formations and the locations were plotted on the base sheet. Measurements along the respective geologic contacts were

generally spaced at horizontal distances of about 500 feet. Because the stratigraphic units dip locally it was necessary to compute the strike and dip of the beds and to correct for the dip angle in determining the stratigraphic thicknesses of the Moenkopi interval. Thickness computations were plotted at the points of altitude measurements along the contact of the Moenkopi and the Shinarump, and isopach lines were drawn at 10-foot intervals on the basis of the distribution of thickness figures. The relatively large number of readings, both for strike and dip of beds as well as for altitude measurements, permitted elimination of certain computations that were inconsistent with regard to the overall mass of statistical data. The locations and depths of channels of Shinarump member as shown by isopach lines based on photogrammetric measurements and plotting were generally in close agreement with those determined by field methods. Details of the photogeologic study are described by Witkind, Hemphill, Pillmore, and Morris (1960).

FACIES CHANGE

Measurements from aerial photographs in conjunction with stratigraphic studies of Cretaceous rocks in northern Alaska have demonstrated the rate and direction of "shaling," or facies change, of certain formations. In the Utukok-Corwin area resistant rocks of the Kukpowruk formation, which is predominantly silty shale, siltstone, and sandstone, overlie less resistant

FIGURE 28.—Diagram of steeply dipping beds showing relation of stratigraphic thickness to dip angle and horizontal distance between top and bottom of bed.

Stratigraphic thickness is determined from the formula

$$t = \frac{d}{\sin \theta}$$

where t = stratigraphic thickness;

d = horizontal distance at right angles to strike line between points at same altitude on top and bottom of bed;

and θ = angle of dip.

rocks of the Torok formation, which is largely clay shale, claystone, and silty shale. The Torok formation commonly forms the lowlands, which are characterized by rather uniform and low-dipping topographic slopes. The Kukpowruk formation forms high, resistant ridges that can be traced many miles. The contact of the two formations is marked by a break in topography that has been mapped in the field in conjunction with the study of aerial photographs. Slopes below the contact are generally smooth and unbroken; slopes above the contact are marked by conspicuous topographic breaks caused by hard, resistant sandstone beds in the basal part of the Kukpowruk formation. Vertical exaggeration of the stereoscopic model accentuates these topographic breaks in slope. Photogeologic and field studies show that these resistant beds pinch out usually in an easterly or northerly direction (see fig. 97). It is significant that their topographic expression is lost. Ground observations along stream cuts indicate that the resistant beds grade laterally into shaly sections.

Quantitative studies from aerial photographs of the amount of section affected by facies change in the Utukok-Corwin area show that several thousand feet of sandy section of the Kukpowruk formation grade laterally to the east and north into shale of the Torok formation. Chapman and Sable (1960) stated that the methods used in these studies included tracing on vertical aerial photographs a resistant unit within the Kukpowruk formation around the flanks of a large open structure and then measuring the stratigraphic intervals between the resistant bed and the contact of the Kukpowruk and Torok formations to determine the new relative stratigraphic positions of the contact in different parts of the area. Photogrammetric measurements were made whenever possible in localities of good field control; a few stratigraphic thicknesses were determined solely by photogrammetric methods without field control. Locations for measurements were chosen along east-west and north-south lines. Relative stratigraphic positions of the contact of the Kukpowruk and Torok formations were then plotted graphically against lateral distances between points of measurement; this resulted in a line whose gradient showed the average rate of rise of the contact between points of measurement. An average eastward-rising gradient of 58 feet per mile and an average northward-rising gradient of 97 feet per mile were calculated.

It was concluded on the basis of plotting these average gradients as vector quantities that a resultant maximum gradient of 115 feet per mile exists and that more than 10,000 feet of sandy beds grade into shaly sections over the area studied. The maximum gradient direction was further interpreted to lie at right angles

to the direction of minimum facies change, which is believed to indicate the general trend of the old shoreline during the period of deposition of the Kukpowruk and Torok sediments. Thus the photogeologic measurement of stratigraphic intervals not only permitted determination of the directions and amounts of facies change, but further allowed inferences concerning the geologic history and environment, which may be significant in the search for petroleum in that area.

STRUCTURE CONTOURING

Structure contours are usually constructed on the basis of a series of spot altitudes, some of which may be photogrammetrically determined at the top of the horizon to be contoured, but many of which will be measured at formation contacts above or below that horizon. Photogeologic procedure is similar to field procedure and requires adjusting the altitudes of all points not on the horizon to be contoured by making appropriate considerations of strike and dip and stratigraphic thickness. Structure-contour lines are then adjusted to the resultant series of altitudes projected to the same formation contact.

NOTOM-15 QUADRANGLE

In photogeologic interpretation and mapping of the Notom-15 quadrangle, Utah, (Hackman and Tolbert, 1955) altitudes for structure contouring were measured using a Kelsh plotter. No previous geologic or topographic mapping had been done in the area; geologic data and altitude measurements were plotted to a control net established by photogrammetric methods. The Notom-15 quadrangle is well-exposed canyon country typical of the Colorado Plateau of Utah. Gently folded sedimentary rocks of Triassic and Jurassic age underlie the area. Canyons transecting the general structure trend made the application of photogeologic procedures ideal. A series of altitude measurements were made along the contact of the Wingate sandstone of Triassic age and the overlying Kayenta formation of Triassic(?) age. The wide exposure of this contact throughout the area permitted sufficient measurements to control structure contouring. Structure contours were then drawn on the top of the Wingate sandstone. Subsequent fieldwork corroborated the general structure as contoured by Kelsh plotter from aerial photographs and also corroborated the distributions of rock formation as interpreted and mapped from photographs. Positioning of other planimetric data, such as streams, was shown to be in excellent agreement with the subsequently compiled standard topographic map of the quadrangle. The positioning of data and altitude determinations by Kelsh plotter thus resulted in a highly reliable geologic map of the area.

DISCOVERY ANTICLINE

Procedures used in contouring the Discovery anticline in northern Alaska included stereometer measurement of altitudes combined with simple trigonometric computations and graphic constructions to compile a generalized structure-contour map (Marshall and Rosendale, 1953). These procedures contrast markedly with the Kelsh-plotter compilation of the Notom-15 quadrangle, but demonstrate that simple methods may be useful in obtaining structural information of a reconnaissance nature from aerial photographs.

Discovery anticline, a gently folded structural feature approximately 25 miles long and 7 miles wide, is underlain primarily by Cretaceous rocks. The area is generally covered with tundra grasses, but resistant beds within the stratigraphic section are expressed topographically as ridges, or breaks in slope, that can be traced for many miles; some beds are expressed by photographic tone due to differences in vegetation (see fig. 40). Dip slopes rarely coincide with topographic surfaces.

Procedures for obtaining and positioning data for structure contouring involved the arbitrary selection of cross-section lines normal to the general structural trend. Strikes and dips of beds were then determined by simple stereometer methods at numerous localities and projected to the nearest cross-section line. Where the strike line did not intersect the line of section at right angles the apparent dip was determined and plotted on the section line. This procedure was fol-

lowed for all strikes and dips, and resulted in cross-section lines along which the different dips were plotted. A marker bed was then selected and its profile along the line of section graphically reconstructed on the basis of the positions and amounts of dip previously plotted (fig. 29). It was assumed that bedding throughout the stratigraphic section was parallel. Structure contours were then positioned along each line of section by further graphic constructions (fig. 30). However, the datum for each line of section commonly was different, depending on which part of the stratigraphic section was expressed in any one local area, and it was necessary to obtain stereometer measurements of altitudes between cross-section lines so that structure contours, as positioned along each line of section, could be tied together (fig. 31). The resulting reconnaissance map, plotted on an uncontrolled photomosaic, indicated the general magnitude and closure of the anticline and the attitude and steepness of bedding. Figures 29-31 show graphic constructions in reconnaissance structure contouring from measurements made with stereometer-type instruments.

DETERMINING DISPLACEMENTS ON FAULTS

The vertical component of displacement on some faults may be readily determined from parallax measurements made on marker beds on opposite sides of the fault by simple conversion of parallax difference to feet or other appropriate unit of measurement. If the fault plane dips, relative altitudes on marker beds may be related to the down-dip component of displacement by trigonometric or graphic solution.

FIGURE 29.—Diagram showing graphic reconstruction of marker bed along line of section.

Dips determined from aerial photographs are first plotted along line of section. The marker bed is then reconstructed by extending bed upward from point *a* at 12° dip for half the distance between *a* and *b*. From this point the bed is extended at 15° dip to a point half the

distance between *b* and *c*. From this point the bed is again extended at 20° dip to a point half the distance between *c* and *d*, and so on. A smooth curve is then drawn to represent the marker bed.

FIGURE 30.—Diagram showing graphic construction in positioning structure-contour lines on top of marker bed and the projecting of these lines to their relative horizontal positions along the line of section.

FIGURE 31.—Diagram showing relation of structure-contour positions along two lines of section at different altitudes.

Relative positions of 50-foot structure contours along each line of section are shown to the right of each line. Absolute altitudes of structure-contour positions are shown to the left of each line of section. Because the zero points on the reconstructed marker bed along lines A and

B lie at 1,350 and 1,400 feet, respectively, it is necessary to connect the 50-foot contour position on line A with the zero contour position on line B, in compiling the structure-contour map.

DETERMINING STREAM GRADIENTS

Stream gradients may be calculated from parallax measurements under certain circumstances. Because many stream gradients are very low—a few feet or tens of feet per mile—an instrument should be used that will permit correction for tilt in the photographs. It will also be desirable to have vertical control for the removal of tilt, as a small amount of tilt not removed from the stereoscopic model could seriously affect the computation of stream gradient. If a stream has a meandering course, then the horizontal distance along the stream between points of measured parallax must be determined by a chartometer or similar instrument for measuring distances along a curved path.

**DIRECT DETERMINATION OF SLOPE
DIPPING PLATEN**

In addition to the indirect determination of slope by the use of parallax measurements in conjunction with trigonometry or graphic solution, direct measurements of some slopes may be made, both from glass-plate dispositives in double-projection instruments and from paper prints. The simplest procedure is with double-projection instruments and involves the use of a modified platen that can be tilted to coincide with the dip of a topographic surface or bedding plane (fig. 32). Because all features of the terrain are optically re-created in the stereoscopic model of double-projection instruments in essentially true relation, the dip of the platen when made to coincide with the ground surface, or to intersect three or more points on a bedding plane, will be a true measure of the dip of that surface. The dip can be measured with a clinometer at-

tached to the platen or by an accessory device such as a "devil level" or Brunton compass. Dips below 40° can be readily obtained by this method, provided topographic expression or rock outcrops permit positioning of the platen. Dips greater than 40° are difficult to determine owing to the difficulty of positioning the dipping platen in the plane of a steeply dipping surface; steep dips should be computed using the parallax methods described above.

STEREO SLOPE COMPARATOR

A unique method for determining angles of slope from paper prints is employed with the stereo slope comparator (fig. 33), which was developed by the U.S. Geological Survey (Hackman, 1956b, p. 893-898). The instrument consists of two gear housings each containing a horizontal shaft on which small targets are mounted that can be fused stereoscopically into a single target. Swing of the horizontal shafts permits positioning the targets in any direction of strike. The gear housings are mounted on sliding tubes that permit the targets to be separated horizontally so that the fused target appears to rise or fall in space, just as the dot in stereometer-type instruments. However, the dip is determined by physical tilting of the target in space. The instrument is unique in that it measures the exaggerated dip of the imaginary slope created by stereoscopic viewing. With vertical photographs of normal 60 percent overlap, most individuals see the terrain exaggerated in height from 2.5 to 3.5 times. The exaggerated dip, recorded on a protractor attachment on the stereo slope comparator, must be reduced to a true dip. This is accomplished by reference to

FIGURE 32.—Dipping platen.

FIGURE 33.—Stereo slope comparator.

INSTRUMENTS FOR DIRECT DETERMINATION OF SLOPE

a slope-conversion graph made up of intersecting lines that represent true angle of slope, exaggerated angle of slope, and exaggeration factor (fig. 34). Construction of the graph is based on the relation

Tangent true angle of dip

$$= \frac{\text{tangent exaggerated angle of dip}}{\text{exaggeration factor}}$$

In determining dips from a pair of paper prints it is necessary to know the exaggeration factor of the interpreter for that stereoscopic model. This factor varies slightly with different individuals and is determined by reference to a supplementary slope chart on which a dipping surface of specific dip has been constructed by methods described by Hackman (1956a, p. 387-391). By measuring the exaggerated dip of this constructed surface, known to represent a given true angle of dip, an exaggeration factor is obtained; it is then possible to make measurements on a specific pair of photographs and to convert any exaggerated dip to a true dip. Because of the difficulty of placing the tilted target in a steeply dipping plane, the instrument is most reliably used where true dips are 20° or less.

DIP ESTIMATION

From paper prints an experienced interpreter can estimate dips, particularly in the range of 1° to 5°, with considerable reliability, as a result of vertical exaggeration in the stereoscopic model. Because of vertical exaggeration, angles of slope in terms of their tangent functions are exaggerated in the stereoscopic models as much as 2.5 to 3.5 times, with the result that low-dipping surfaces, which are in places difficult to observe in the field, are readily interpreted (figs. 45, 88, 90, 91, and 97). For example, a true dip of 1° may appear to be a dip of 3° or 4° in the stereoscopic model, and a dip of 5° may appear to be 15° to 20°. For true dips below 20° an error of a few degrees in estimating the exaggerated dip has only a small effect on the true dip (see fig. 35), and an interpreter is able to make reliable visual determinations of these dips from most stereoscopic models. But steeply dipping surfaces are also exaggerated and made more difficult to evaluate. Any small error in determining the angle of exaggerated dip of steep slopes results in a relatively larger error in the true dip calculation for that slope. Brundall and Harder (1953, p. 150) stated that "the accuracy of individual estimation is generally inversely proportional to the steepness of dip." In estimating dips a correction obviously must be made for the oversteepened slopes as they appear in the stereoscopic model (see figs. 34 and 35).

Factors affecting vertical exaggeration in stereoscopic models have been discussed by several writers (Treece, 1955; Goodale, 1953; Thurrell, 1953; Miller, 1953; Aschenbrenner, 1952; and Stone, 1951), but complete agreement has not been reached concerning the effects of specific factors such as viewing distance and image separation. However, once an interpreter has correlated amounts of dip, determined photogrammetrically or by field procedure, with a given set of conditions such as type of stereoscope, focal length of photography, photobase, and image separation, reliable estimates of true dip can be made over wide areas without reference to known dips.

OTHER METHODS OF DETERMINING ANGLES OF SLOPES

Another method of determining slopes in stereoscopic models is based on the floating-line principle. Brundall and Harder (1953, p. 150-151) briefly mentioned a device consisting of two lines scribed on plastic plates. The lines, seen stereoscopically as a single line floating within the model, can be made to converge so that the floating line appears to plunge in space. The plunging floating line is placed in the component of dip direction at right angles to the flight line. The angular rotation of the scribed lines required to obtain a given amount of steepness of plunge of the floating line is then related to true dip by means of a graph. As this method would result in true dip only for beds striking parallel to the flight line, the correction graph must also consider the azimuth of the dip component observed with respect to the strike of the beds.

Wallace (1950) has used angular relations in the plane of the aerial photograph as the basis for a method of determining strikes and dips from aerial photographs. The method is best applied where erosion has exposed bedding trace lines as contrasted to broad topographic surfaces that coincide with bedding. No parallax measurements are required. It is necessary to measure the angular relation of two bedding trace lines with respect to a known or assumed azimuth line on each photograph of a stereoscopic pair and to determine the plunge of the line of sight from the camera position to the outcrop, or bedding-trace line. These data are then plotted on a stereographic net to determine the strike and dip of the bed (Wallace, 1950, p. 275).

OTHER METHODS OF DETERMINING QUANTITATIVE DATA

Measurement of geologic data, other than altitudes and direct determinations of slope angles, are only infrequently made from aerial photographs. However, the possible applications of light-transmission measurements, from both black-and-white and color pho-

FIGURE 34.—Slope-conversion chart showing relation of exaggeration factor, exaggerated slope, and true slope.

FIGURE 35.—Diagram, based on tangent functions, showing relation of true dips to exaggerated dips seen in stereoscopic models.

tography, light-reflectance measurements, measurements related to heat-retention characteristics of terrain photographed, infrared absorption, size, frequency, and orientation measurements of physiographic features, and perhaps others, offer challenging opportunities for future study (see Ray and Fischer, 1960).

PLOTTING

Map compilation—planimetric positioning of data—is basic to most geologic studies and generally requires

methods of plotting data orthographically. Thus, data plotted or interpreted on vertical aerial photographs, most of which are perspective in view, must be replotted on an orthographic base. The orthographic base may be planimetric or topographic. Where no base map exists perspective aerial photographs provide a medium for constructing a control layout on which geologic and other data may be plotted orthographically.

CONSTRUCTION OF CONTROL LAYOUT

A control layout is an orthographic plot of a series of points selected on aerial photographs that cover a given area. These points are used to control the positioning of data plotted from the perspective photograph. Plotting, or transfer, of data from the photograph may be done with simple overhead projectors or sketchmasters under some circumstances, or with stereoplotting instruments described above. The accuracy of the final plot will depend primarily upon the control net and the instrument used in plotting (see p. 74-75).

Basically a control layout or control net is established by triangulation from the aerial photographs in much the same manner as field triangulation is carried out. This aerial triangulation requires mechanical construction of templates which are assembled together into the triangulation network. There are two general methods of constructing templates. One method involves radial triangulation using the principal point of the single photograph as a principal triangulation station to construct radial templates; the other method involves radial triangulation using some orthographically positioned pass point from the stereoscopic model as a principal triangulation station to construct stereotemplates.

Where single photographs are used for triangulation it is generally assumed that the photographs are truly vertical and have no tilt; relief displacement is radial from the photograph centers. However, a tilt of 1° or 2° does not significantly affect horizontal positioning over small areas. Templates from single photographs may be constructed by the hand-templet method, the radial-arm ("spider"-templet) method or the slotted-templet method. Photographs are first prepared by marking the centers, conjugate centers, and selected pass points, usually six in number, along the margins of a photograph; pass points are selected which are common to adjoining flight strips and common to succeeding and preceding photographs within the flight strip. From each photograph, azimuth lines are then constructed from the photograph center through all other selected points to form a templet for that photograph. Azimuth lines may be drawn in pencil on an overlay sheet (hand-templet method); they may be constructed of metal arms ("spider"-templet method), or they may be cut as slots in a piece of cardboard (slotted-templet method). After templates have been constructed for all photographs they are assembled into a triangulation network in which the intersections of azimuth lines locate the orthographic positions of the points selected. The result is a base sheet with a series of points located

in their correct relative horizontal positions. Where horizontal control points are available, the distance between plotted positions of any two of them determines the scale of the control layout. Details of constructing and assembling these templates are described by Kelsh (1952, p. 419-429).

Construction of stereotemplates requires the use of a stereoplotting device to plot selected points common to adjoining flight strips and within the flight strip. The templet is actually a double templet of the area of the stereoscopic model rather than the single photograph. Azimuth lines are constructed for each part of the templet using one of the pass points as a principal triangulation station for one part of the templet, and using a different, generally diagonally opposite, pass point as the principal triangulation station for the second part of the templet. These two parts are joined together to form the completed templet for each stereoscopic model. Details of constructing and assembling the stereotemplates have been described by Scher (1955). Because of the longer base line of stereotemplates the resulting triangulation network is said to have a stronger scale solution than can be obtained from radial templates constructed from single photographs. Other photogrammetric advantages are mentioned by Scher (1955).

ORTHOGRAPHIC POSITIONING

PLOTTING ON ORTHOGRAPHIC BASE MAPS OR CONTROL LAYOUTS

The main objective in orthographic plotting of geologic data is to show the true planimetric relations of geologic features by removing relief and tilt displacement that may be present in perspective vertical aerial photographs. Relief displacement is commonly large, but tilt displacement is generally small and is usually disregarded when positioning geologic data on a planimetric base sheet. When positioning geologic data to a topographic base both relief and tilt displacement may be significant and require plotting from a leveled stereoscopic model. For horizontal positioning of data to a planimetric base in areas of low relief the relief displacement will be small; overhead projectors may be used to transfer data from the photograph to base map or control net. For example, with common photography of 1:20,000 scale taken with a 6-inch-focal-length lens, radial displacement near the edge of the photograph will only amount to about 0.1 inch where topographic relief does not exceed 300 feet. Basically relief displacement of a given amount of relief is a function of flying height and is independent of focal length and scale (see p. 74-75).

Where relief displacement is excessive it is possible

to change the photograph scale by racking the overhead projector up and down and, provided base map control is sufficiently dense, to scale small areas of the photograph to the base, thus compensating for much of the radial displacement of the perspective photograph. The reliability of the final plot will be in part a function of the density of control points on the base. The suitability of the final plot will depend on the geologic objective. On most radial triangulation networks it is common to find eight control points, exclusive of the photograph center, for each photograph; this number of points will not normally be sufficient to give a reliable plot of the geologic detail in areas of moderate or high relief unless a stereo-plotting instrument is used. The vertical sketch-master, in which the image of a single photograph is seen superposed on the base map or control sheet, generally is used in the same way that overhead projectors are used in plotting. The same general limitations of the overhead projector apply to the sketch-master; that is, radial displacement due to moderate or high relief cannot be effectively removed.

Orthographic plotting may also be accomplished with the radial planimetric plotter (fig. 14), or with the more complex paper-print plotters, such as the KEK or Mahan plotters. (See p. 42, 45). The radial planimetric plotter is the simplest to operate. It is easily scaled to control points on the base map or triangulation network and effectively corrects for the radial displacement of vertical aerial photographs. Fine detail, such as the configuration of reentrants in contact lines, may be lost in plotting, however. Tilt inherent in photographs cannot be eliminated, but horizontal positioning due to small amounts of tilt found in present-day photography do not significantly effect horizontal positioning of photographic detail for most geologic interpretations. The KEK and Mahan plotters may also be used to plot geologic data from paper prints. These instruments permit compensation for any inherent tilt that may be present in the photographs but are more difficult to operate than the planimetric plotter.

Whenever paper prints are used in plotting or transferring geologic data to base maps or control sheets it may be desirable to annotate, or mark, the geologic features to be transferred. This is particularly desirable when overhead projectors are used and is usually a necessity for all instruments if someone other than the interpreter is to do the plotting.

Double-projection instruments afford a high degree of reliability in plotting geologic data from aerial photographs. The ability to correct for tilt and relief displacement combined with an enlarged view

of the stereoscopic model when the Kelsh, multiplex, or ER-55 plotters are used permits a highly reliable compilation of geologic data. Even when vertical control is lacking, it is possible to remove most of any tilt inherent in the stereoscopic model by careful reference to physiographic manifestations of tilt such as oversteepened or reverse stream gradients, tilted meanders of a stream, or tilted bodies of standing water (see p. 55).

True orthographic positioning is not always attained, however, in geologic compilations from aerial photographs. Not only is there a question at times of the reliability of interpretation because of the subjective nature of much photogeologic study, but the various instruments themselves have differing degrees of accuracy inherent in their construction. Positioning of clearly identified geologic features by overhead projector, which does not permit adjustments for tilt or effective removal of relief displacement, would be far less reliable under most circumstances than positioning by double-projection instruments. However, the geologic product sought should determine in part the procedure to be used in plotting. Normally there is no reason to use an instrument that will plot detail more accurately than is needed to satisfy the geologic requirement. For example, in small-scale reconnaissance mapping, it is hardly necessary to use a precision plotting instrument for horizontal positioning. The problem of instrument requirement in relation to the geologic problem is further considered under a discussion of interpretation and plotting systems (see p. 69-75).

Only where a significant saving in time and money can be shown is it justifiable to use an instrument whose capability exceeds the minimum requirements of the geologic problem. Such a condition may exist for example where small-scale photographs of an area are available. Much of the United States is now covered by photographs at a scale of approximately 1:60,000. The use of such small-scale photographs in an instrument such as the Kelsh plotter may reduce by as much as 90 percent the number of stereoscopic models that would normally be oriented for interpretation, measuring, and plotting if 1:20,000-scale photographs were used. Even when 1:20,000-scale photographs are used with simple instruments the common practice is to separate the operations; that is, the stereoscope is used to interpret geologic detail and another instrument, such as the stereometer, is used to determine vertical measurement. Thus, by using a precision plotter, which combines interpretation, measuring, and plotting, a significant saving in time and money may be expected.

PLOTTING ON ORTHOPHOTOGRAPHS

An orthophotograph is a photograph that has the position and scale qualities of a map. In addition it has the abundant imagery of the conventional perspective photograph and hence a wealth of photographic detail (fig. 47). Theoretically the orthophotograph, with tilt and radial displacement eliminated in preparation (Bean and Thompson, 1957), has the desirable detail of a photograph and the geometric characteristics of an accurate planimetric map. The method of constructing the orthophotograph from double-projection stereoscopic models results in a small loss of photographic resolution, but horizontal positioning accuracy is comparable to that of the standard topographic map of the same scale.

The orthophotograph, when viewed with an alternate perspective aerial photograph, forms a stereoscopic model, although with only a small amount of stereoscopic relief as contrasted to viewing two perspective photographs. In viewing an orthophotograph with a perspective photograph it is generally best to use the same perspective photography as was used in the preparation of the orthophotograph. Combining the orthophotograph with a perspective photograph permits plotting of geologic detail from the perspective photograph to the orthophotograph and gives a reliable photomap. Geologic data on the orthophotograph then can be transferred by direct projection to a topographic or other base, if desired, or merely traced off to give a reliable planimetric map of areas where no base maps exist. As an aid to field geologic mapping, in which a daily plot of observed data is desirable, the orthophotograph may be especially helpful.

The range of potential applications of orthophotography has been summarized by Bean and Thompson (1957, p. 178) who stated that " * * * whenever there is an advantage in being able to determine accurately on an aerial photograph the positions of points, the lengths or directions of lines, the courses of curved lines, or the shapes or areas of given tracts, the orthophotograph offers a potential means of accomplishing the desired end." In addition, as the basis for constructing mosaics the orthophotograph has a significant application, especially in areas of moderate or high relief.

PLOTTING ON GRIDDED BASE MAPS

Gridded base maps may be especially valuable for field plotting of geologic data without the assistance of photogrammetric instruments. In constructing a gridded base map a grid made up of small squares, usually 1 centimeter on a side, is first superposed

photographically onto the perspective aerial photograph. The same grid is then orthographically transferred to the base map by a photogrammetric technician using stereoplotting instruments (Landen, David, oral communication, 1958). The grid lines are straight as superposed on the perspective photograph but are curved on the base map (figs. 115 and 116). By dividing the photograph into many small grid squares the effects of tilt and relief displacement become so small as to be negligible within any one square. Information sketched within grid squares on the perspective photograph is transferred visually to the base map by matching grid squares on the photograph with those on the map. The method may be especially useful in the field where it is desirable to keep a compilation of each day's work.

VERTICAL POSITIONING IN CROSS SECTIONS

In addition to the orthographic positioning of photogeologic data on base maps it is commonly desirable to plot geologic cross sections. The third dimension of the stereoscopic model is then added in part to the normal two-dimensional planimetric presentation of geologic information. Vertical positioning of geologic data, as shown in cross section, may be helpful to the geologist interpreting the aerial photographs of an area, as well as to the map reader who may be less familiar with the geology of the area.

Cross sections are easily and rapidly constructed with a profile plotter from stereoscopic models in double-projection plotters. Modification of the tracing table permits profiles to be drawn in any direction within the stereoscopic model (figs. 19 and 20). Sections may be drawn at a horizontal-vertical ratio of 1:1 or they may be exaggerated as much as 5 times. When a 1:1 ratio is used, dips of beds or components of dip, stream gradients, thickness of beds, and similar data may be obtained directly from the section. Exaggerated profiles may be desirable where relief of terrain is low, or, for example, when interpreting the significance of vertical position of thin stratigraphic units in correlation studies. Vertical positioning in sections may also show information suggesting the presence of faults.

INTERPRETATION, MEASURING, AND PLOTTING SYSTEMS

An interpretation, measuring, and plotting system (see fig. 36) may be defined as a combination of photographs and instruments that will permit attaining specific qualitative and quantitative geologic information from stereoscopic models. The optimum system is generally achieved by combining the minimum

FIGURE 36.—Photogrammetric systems for geologists.

scale photographs and minimum instrument capability that will provide the desired geologic measurements within given accuracy requirements. That is, the scale of photographs should be the smallest that will permit differentiation of photographic detail needed for qualitative interpretation, as well as the smallest that will permit photogrammetric measurements within specified limits. Fundamentally, the geologic objective of a particular study is the controlling factor in the choice of the optimum system of interpretation, measuring, and plotting. The geologic objective may permit the use of existing instruments and photograph scales or it may necessitate new photography or instruments to attain given accuracy requirements.

The type of geologic map and its intended use—the geologic objective—can be considered on the basis of accuracy requirements or limits of error, both in obtaining vertical measurements and in plan positioning of geologic features, provided photographic detail is adequate for qualitative interpretation. For example, a detailed structure-contour map may require an accuracy of vertical measurement within ± 5 feet of altitude and a horizontal position of geologic features within $1/25$ inch of true map position. In contrast a small-scale structure-reconnaissance map for planning purposes may permit a vertical tolerance of ± 50 feet and have only general horizontal positioning requirements. Thus the choice of an interpretation, measuring, and plotting system may be reduced to certain mathematical requirements that can be satisfied by combining instrument capability with appro-

priate photography; or the geologic objective or tolerances of measurement may be modified to permit the use of existing photography and instruments.

However, geologic maps, unlike topographic maps, have no standard accuracy limits except those imposed by the individual geologist, with the one exception in the Geological Survey that solid lines, representing faults, contacts, or similar geologic features, should generally be within $1/25$ inch of their correct map positions for general geologic maps at a scale of 1:63,360 or larger. Horizontal positioning of data within $1/25$ inch of true map position may be accomplished with almost any plotting instrument or plotting system, especially if relief of the area is low and excessive tilt is not present in the photographs. Hence, the vertical-accuracy requirement specified by the geologist for a given geologic problem is ideally the determining factor in choosing an interpretation, measuring, and plotting system. This accuracy requirement, as well as the maximum range of measurements expectable for any system, may be equated against instrument capability and photograph scale as follows:

Geologic requirement of vertical-measurement accuracy	Instrument capability in terms of K and V factors (see fig. 37).
or Expected maximum range of vertical-measurement error	

Figure 37 is an elaboration of this equation and shows the general relations between the geologic requirements of vertical accuracy or expected maximum error in measuring spot altitudes or vertical intervals

GEOLOGIC REQUIREMENT OF VERTICAL-MEASUREMENT ACCURACY OR EXPECTED MAXIMUM RANGE OF VERTICAL-MEASUREMENT ERROR, IN TERMS OF INSTRUMENT CAPABILITY

PHOTOGRAMMETRIC INSTRUMENTS THAT MAY BE USED

FIGURE 37.—Photogrammetric measuring and plotting systems for geologists showing relation of different instruments to vertical-measurement and horizontal-positioning errors.

where K factor = difference in altitude, in feet, on the ground per unit of vertical measurement in an anaglyphic-type model, that is, per 0.1 millimeter

$$= \frac{\text{model-scale denominator}^2}{3,048}$$

where V factor = difference in altitude, in feet, on the ground per unit of measurement from a parallax bar or a paper-print plotter, that is, per 0.01 millimeter

$$= \frac{\text{flying height (feet)}}{\text{photobase (millimeters)} \times 100}$$

¹ No excessive tilt assumed to be present for paper-print models that cannot be leveled.

² Model scale for Kelsh plotter is usually about 5 times original photography scale; for ER-55 usually about 3.5 or 5 times, depending on the projector model; and for multiplex usually about 2.5 times.

in terms of instrument capability on one hand and photogrammetric instruments that may be used for measuring and plotting on the other hand. The determination of spot altitudes or relative vertical intervals satisfies most geologic requirements of altitude measurements from stereoscopic models and permits construction of structure-contour lines, and isopach lines, and the determination of dips of slopes, displacements on faults, and similar data. Figure 37 can be used in choosing the best selection from existing photograph scales and instruments for measuring vertical distances, or it can be used to determine what combination of photograph scale and instruments would be optimum in making vertical measurements within certain specified tolerances. For economic reasons the geologist more often than not will be concerned with the best selection of existing photographs and instruments but this selection may not be the optimum interpretation, measuring, and plotting system. This may require modification of his geologic objective, at least in reporting the limits of measurement.

INSTRUMENT CAPABILITY

Instrument capability, selected as the principal basis for the systems shown in figure 37, is an empirically derived factor generally considered with respect to topographic mapping systems as the minimum contour interval—stated in terms of a fraction of the flying height—that can be plotted to fulfill certain accuracy requirements. For geologic measurements it is desirable to consider instrument capability as the minimum increment of vertical measurement that generally can be determined by the geologist from the stereoscopic model. This permits a simple evaluation of expected maximum errors in geologic measurements when double-projection stereoscopic models are used, or when stereoscopic models from paper prints are used. It also allows the geologist to determine what photograph scale and instrument combinations will give him a desired accuracy of measurement. Because the minimum increment of vertical measurement is empirically derived, the limits of error for vertical measurements described below may be subject to modification.

To determine the expected maximum error for a given combination of photograph scale and instrument three possible individual errors must be considered. These are (a) instrument capability in terms of the geologist's ability to measure horizontal linear parallaxes and increments of vertical measurement, (b) curvature of the datum within a stereoscopic model when double-projection instruments are used, or paper and lens distortions when paper prints are used, and (c) tilt. Consideration of the cumulative effect of

all three possible errors is necessary in determining the expected maximum error for a particular measuring and plotting system, except for leveled models where tilt has been eliminated. In measuring spot altitudes or relative intervals these errors may be compensating rather than cumulative and therefore many measurements will be well within the expected maximum error determined for a particular combination of photograph scale and instrument.

Experience has shown that for double-projection plotters, it is generally possible for the geologist to determine any one reading to one unit of vertical measurement. One unit of vertical measurement is equal to 0.1 millimeter. With care the increment of measurement may be read closer than one unit of vertical measurement. The amount of altitude difference, in feet, on the ground represented by one unit of vertical measurement in the model—called the K factor—depends solely on the scale of the projected stereoscopic model, and is determined by the ratio

$$\frac{\text{Model-scale denominator}}{3,048}$$

This factor is constant throughout the stereoscopic model. Hence spot altitude readings generally may be read within an amount equal to $\pm K$, that is, the geologist may read a point one unit (0.1 millimeter) too high or one unit (0.1 millimeter) too low. In addition, an error of $\pm K$ is added for curvature of the model datum. Thus the maximum error for spot altitudes can be expected to be on the order of $\pm 2K$ for models leveled to vertical control. Where errors due to reading and to curvature of the datum are compensating a minimum error approaching zero can be obtained. For interval measurements the altitudes of two image points in the stereoscopic model of course must be measured. Each point may be read within an amount equal to $\pm K$, or a total reading error $\pm 2K$. Curvature of the model datum may affect the reading of each point a similar amount and can be disregarded when relative intervals are measured on points close together in plan view; for points close together the expected maximum error generally will be similar to that for spot altitudes. But if points of measurement are not selected close together an added error of $\pm K$ due to datum curvature may be introduced. Thus the maximum error for relative interval measurements is on the order of $\pm 3K$ (figs. 37 and 38).

When vertical control is absent many double-projection stereoscopic models and some models from paper prints may be leveled visually to within 1° of a horizontal datum by observing certain physiographic

FIGURE 38.—Diagram showing datum-curvature relation to maximum expected error in measuring vertical intervals from leveled double-projection stereoscopic model.

Let AB equal the interval desired. If the upper point is measured at A' an error equal to $-K$, or one unit of measurement, may result from datum curvature; when point B' is measured an error of $+K$ may result. If points A and B' are chosen for measuring the interval and point A is measured one unit too high (equivalent to $+K$) and point

B' is measured one unit too low (also equivalent to $+K$) a maximum expected error, including datum-curvature error, of $+3K$ may result. Likewise if points A' and B are chosen for measuring the interval a maximum expected error, including datum-curvature error, of $-3K$ may result.

features in the model (see p. 55) and making appropriate instrument adjustments. For double-projection stereoscopic models that are leveled visually some error due to tilt thus may be present in addition to possible errors in reading and curvature of the model datum; the order of maximum error for spot altitudes becomes $\pm 2K \pm$ error due to tilt, and for relative interval measurements becomes $\pm 3K \pm$ error due to tilt. When relative stratigraphic thicknesses, displacements on faults, or similar geologic measurements are being made, errors due to tilt or from curvature of the model datum may be minimized by measuring points close together in the stereoscopic model. For points spaced far apart the error due to tilt can exceed the error in reading intervals.

Limits can also be placed on reading units of measurement with paper-print plotters or parallax bars, except that a V factor rather than a K factor is employed. A differentiation of factors is necessary as the V factor, unlike the K factor, is not constant throughout the model, but varies slightly due to differences in scale at different altitudes in models formed from paper prints. For practical purposes, V is the ratio:

$$\frac{\text{Flying height (feet)}}{\text{Photobase (millimeters)} \times 100}$$

The V factor represents the difference in altitude in feet on the ground per unit of measurement from a parallax bar or paper-print plotter, that is per 0.01 millimeter. Experience has shown that parallax meas-

urements from paper prints may be read within about ± 0.02 millimeter or $\pm 2V$. Considering possible errors due to paper or lens distortion and due to tilt, total expected errors for spot altitudes and relative intervals may be determined as shown on figure 37. (See also p. 74.) Errors resulting from paper and lens distortions are considered to be equivalent to about two units of measurement or about $2V$.

Thus two different factors are considered in relating geologic accuracy requirements or expected maximum vertical measurement errors to photograph scale and instrument capability. These factors are the K factor for use with stereoscopic models from glass plates in double-projection plotters, and the V factor for use with stereoscopic models formed from paper prints. For any given system of measurement it is likely that many measurements will fall well within the expected maximum errors as determined from figure 37, especially if high-resolution photographs are available that may permit reading units of vertical measurement less than K or V , and if points of measurement are carefully chosen. Also, errors of reading and datum curvature or tilt may be compensating rather than cumulative, as stated above. In a recent test of determining altitudes of gravity stations with multiplex leveled to vertical control, Kinoshita and Kent (1960) found that 96 per cent of the points measured fell approximately within the limits of $\pm K$ and that 71 percent of the points measured fell approximately within the limits of $\pm K/2$. Results of this special test do not represent the general order of vertical ac-

curacy that geologists may expect to obtain by photogrammetric methods, but they do suggest that many measurements made will be well within the limits shown in figure 37.

RELATION BETWEEN INSTRUMENT CAPABILITY, SCALE, AND VERTICAL MEASUREMENTS

Let it be desired to determine the accuracy of spot altitudes for compiling a structure-contour map of an area covered by recent, high-quality 1:20,000-scale photography flown at 10,000 feet. Adequate vertical control is available for leveling stereoscopic models and a Kelsh plotter is available for measurement and compilation. The expected maximum error shown in figure 37 for spot altitudes for leveled models is $\pm 2K$. Because the scale of the Kelsh model is approximately 5 times that of the original 1:20,000-scale photography (fig. 37), a projected stereoscopic model at a scale of 1:4,000 would result. Thus the K factor for this model would be $4,000/3,048$ or 1.31 feet (fig. 37). Spot altitude measurements could be expected to be correct within $\pm 2K$ or ± 2.62 feet for most points in the model.

Many geologists will have only paper prints and simple measuring devices to use so as a second example let it be desired to determine the expected maximum error in measuring a stratigraphic interval with a parallax bar and paper prints already available. Photographs at a scale of 1:20,000 and taken at 10,000 feet are available. Inspection of physiographic characteristics of the terrain indicates that very little tilt, estimated not to exceed 1° , is present. Rock units are clearly expressed, the formations are essentially flat lying, and points of measurement are within $\frac{1}{4}$ inch on photographs or a distance of about 400 feet on the ground. The photobase distance is 90 millimeters. Figure 37 shows that with parallax bar the expected range of error for relative intervals is $\pm 6V$ $\pm$ error due to tilt,

$$\text{where } V = \frac{10,000}{90 \times 100} = 1.1 \text{ (fig. 37).}$$

The maximum error due to tilt, however, could amount to 14 feet in this example and thus a total expected error of 20.6 feet could result. But the reading error plus paper and lens distortion error may well be less than $\pm 6V$ and the points of measurement may well lie in a direction other than the maximum tilt direction; thus, a measurement error of much less than 20.6 feet will probably result. Figure 37 is constructed to show only the order of maximum error. The percentage of error will depend on the total thickness of the stratigraphic interval; the percentage of error becomes smaller as the thickness of the interval increases.

The geologist will be concerned generally with the expected maximum error of measurement that photographs and instruments already at his disposal will give, and figure 37 is readily used to determine expected maximum errors of measurement for a given photograph scale and instrument combination. However, to determine what photograph scale and instrument combination would be needed to attain specified accuracy requirements is not so easy, as the photograph scale and instrument may be varied and yet give the same required tolerances of vertical measurements. For practical purposes it may be best to equate the vertical-accuracy requirement against instrument capabilities, and to determine from this the scale of photographs that would be needed. Thus, if a requirement for measuring vertical intervals of ± 5 feet is specified it can be seen, for leveled double-projection stereoscopic models, for example, that $\pm 3K$, the maximum expected error for relative intervals, must equal 5 feet or K must equal 1.66 approximately. It follows (see fig. 37) that the projected model-scale denominator must equal $1.66 \times 3,048$ or about 1:5,000.

The scale of photographs required to provide a projected stereoscopic model of 1:5,000 depends on the double-projection plotter used. For the Kelsh plotter, the original photography scale would be approximately 1:25,000; for the ER-55 plotter, approximately 1:17,000 or 1:25,000 depending on the projector model; and for the multiplex, approximately 1:12,000 (fig. 37). Similar computations can be made for other instrument capabilities and requirements of vertical measurements. Where two different combinations of instruments and photograph scales will provide the desired accuracy of vertical measurement, the optimum interpretation, measuring, and plotting system will be determined by the smallest scale of photography that will allow recognition and qualitative interpretation of geologic features pertinent to the given geologic objective.

HORIZONTAL POSITIONING

Horizontal positioning within $1/25$ inch of true map position generally can be accomplished at photograph scale or smaller with any of the plotting instruments that removes relief and tilt displacement. Such instruments include the double-projection plotters and some of the paper-print plotters. The small amount of tilt inherent in present-day vertical photography is generally of little significance in horizontal positioning of geologic features, however, and the radial planimetric plotter may also be used to plot geologic features within $1/25$ inch of true map position. Orthophotographs may also be used for reliable horizontal positioning of data (see p. 69). In addition, geologic features in areas of

low relief may be plotted within 1/25 inch of true map position by sketchmaster or overhead reflecting projector if tilt is negligible. Where relief is low, radial displacement (also called relief displacement) of image points is commonly less than 1/8 inch. For example, on vertical photographs taken from a flying height of 10,000 feet, displacement where the relief is 100 feet amounts to 1/25 inch at a point 4 inches from the center of the photograph. Nearer the center of the photograph the displacement is less. Thus, geologic data on such photographs can be plotted generally within 1/25 inch at photograph scale or smaller with simple overhead reflecting projectors, or can even be traced directly from the photographs and still be within the 1/25-inch tolerance for general geologic maps. The amount of radial displacement, m in inches, is determined from the formula

$$m = \frac{rh}{H}$$

where r =radial distance on the photograph, in inches, from principal point to base of image displaced;

h =height of object displaced, in feet above datum (height of terrain);

and H =flying height, in feet, above datum;

(h and H must be referred to the same datum and be measured in the same units. The amount of displacement, m , is then in the same units of measure as chosen for r). Thus, the limit of relief that can be adequately plotted within the 1/25-inch tolerance for general geologic maps is basically a function of flying height and not of focal length. Displacement due to relief varies inversely with flying height.

Stereoscopic pair

Approximately 1 mile

FIGURE 39.—POORLY RESISTANT PYROCLASTIC ROCKS OVERLAIN BY RESISTANT CAPPING FORMATION (COLORADO).

[Approximate scale 1:20,000. Photographs by Soil Conservation Service]

Coarse pyroclastic rocks, A, are highly dissected in contrast to the more resistant and protecting welded tuff cap-rock, B, in this area of flat-lying formations. Deep dissection of pyroclastic rocks, occurring here preferentially on one slope, permits delineation of contacts that can be traced into nearby areas where strong dissection has not taken place. The use of the floating-dot reference mark of

many photogrammetric instruments may be especially helpful in tracing a geologic contact from an area where the contact is well expressed to an area where the contact is obscured. Sandstone and shale below the pyroclastic rocks are in large part poorly exposed because of the slope wash that covers the deposits.

FIGURE 40.—AREA UNDERLAIN PREDOMINANTLY BY GENTLY FOLDED SANDSTONE, SHALE, CONGLOMERATE, AND GRAYWACKE (NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

In some areas where outcrops are sparse or lacking bedding may be traced on the basis of topography and vegetation. Resistant beds of sandstone and conglomerate cause small topographic rises, in some areas as little as 2 feet, which are easily discerned in the stereoscopic model because of vertical exaggeration present in viewing most stereoscopic pairs. The steepened slope caused by the resistant bed is commonly populated with a different mossy and grassy vegetation from that of surrounding areas, and bedding is revealed as wide, strongly curved bands of vegetation that are recognized on photographs by their lighter or darker photographic tone than surrounding areas. Such

bands of vegetation, as at A, are commonly seen clearly on aerial photographs or from a distance on the ground, but are not always readily distinguished when standing directly on them on the ground.

Permafrost is shown by the presence of beaded drainage, indicated by isolated pools of water connected by short, incised watercourses along main stream. Striped slopes, B, are typical but not unique to permafrost areas (contrast fig. 53). Note high-center polygons, C, that exhibit raised centers surrounded by depressed dark-toned edges. Angular drainage channels, D, are related to melting out of ice wedges and are common in permafrost areas.

FIGURE 41.—EXTRUSIVE VOLCANIC ROCKS AND ASSOCIATED CINDER CONE (UTAH).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Cinder cone, *A*, is readily identified on the basis of shape of the constructional landform. Associated flows, *B*, are dark toned, irregular in ground plan, and marked by very uneven topographic surfaces. Many lava flows lack sur-

face drainage rills, which suggests permeable material. Note especially the lack of surface drainage channels on flanks of cinder cone.

FIGURE 42.—FLAT-LYING SANDSTONE (SOUTHERN UTAH).

[Approximate scale 1:20,000. Photographs by U.S. Geological Survey]

Prominent wide-spaced joints are shown by many short lineations. Where beds are essentially flat lying, joints commonly form in a right-angle pattern and give the terrain a blocky appearance locally, although one direction of jointing may dominate and give a conspicuous linearity

to the topographic grain. The light photographic tone and coarse-textured drainage is typical of coarse sedimentary rocks. Major drainage is dendritic; this pattern is commonly characteristic of flat-lying rocks. Minor drainage is controlled by joints.

Approximately 1 mile

Stereoscopic pair

FIGURE 43.—SANDSTONE AND CONGLOMERATE BEDS INTRUDED BY DIORITE PORPHYRY LACCOLITH (UTAH).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Conspicuous contrast in vegetation results from different lithologic types. Sandstone and conglomerate beds, *A*, are covered largely with scattered tall jack, yellow, and ponderosa pine trees. Diorite porphyry, *B*, is covered with scrub oak as much as 10 feet high. This dense growth of

scrub oak forms a photographic texture that contrasts with areas covered with pines. Note serrated edges of bluffs, *C*, which are expressions of joints in sandstone and conglomerate beds.

FIGURE 44.—GENTLY DIPPING BEDS OF SANDSTONE, SILTSTONE, AND CONGLOMERATE THAT LOCALLY CONTAIN CHANNEL-FILL DEPOSITS (ARIZONA).

[Approximate scale 1:20,000. Photographs by U.S. Geological Survey]

Light photographic tone of rocks, *A*, is typical of massive crossbedded sandstone in this area. Dark-toned rocks, *B*, are reddish thin-bedded shaly siltstone, shale, and fine-grained sandstone. Light-toned conspicuously jointed rocks, *C*, are uranium-bearing sandstone, conglomerate, and mudstone. Locally the dark-toned rocks have been eroded by channel scour, and the channels have been filled with sandstone and conglomerate that now lie unconformably on the older rocks. Erosion of dark-toned rocks along line *D*, which represents the line of unconformity and orientation of a channel in this area, is conspicuous by the photo-

graphic tone change. At *E* the dark-toned rocks have been completely eroded away and light-toned jointed sandstone and conglomerate rest on the light-toned massive crossbedded sandstone. At *F* the dark-toned rocks again become conspicuous where overlying rocks thin. Differences in stratigraphic thicknesses of the dark-toned rocks, which reflect a thickening of overlying rocks that were deposited in old river channels, can be measured photogrammetrically. Isopach lines may be drawn to indicate the orientation of the channel and the general depth of the channel.

Stereoscopic pair

Approximately 1 mile

FIGURE 45.—GNEISS, SCHIST, AND GRANITE FLANKED BY DIPPING SEDIMENTARY ROCKS TRUNCATED BY PEDIMENT GRAVEL (COLORADO).

[Approximate scale 1:21,000. Photographs by U.S. Air Force]

Topographically high, vegetated area, *A*, is underlain by gneiss, schist, and granite. Light-toned sedimentary rocks, *B*, lying unconformably on the igneous and metamorphic rocks, are primarily arkose and sandstone. Trace of unconformity between sedimentary rocks and igneous and metamorphic rocks is indicated by break in slope, *C*, which is locally accentuated by contrast of trees on steep slope

uphill from the trace of the unconformity with grassy vegetation on the gentler slope below. Note effect on dip of vertical exaggeration in the stereoscopic model. The arkose and sandstone unit dips about 25° . The grass-covered pediment gravel, *D*, which truncates the underlying sedimentary rocks, dips 2° to 3° .

Approximately 1 mile

Stereoscopic pair

FIGURE 46.—LANDSLIDE AREA (COLORADO).

[Approximate scale 1:37,000. Photographs by U.S. Geological Survey]

Landslides are indicated primarily by landform. Note the characteristic hummocky topography of slide material prominent at A. Minor ridges of the slide area are commonly parallel to the contour of the slope; clumps of vegetation locally are oriented parallel to the contour of the slope also. Poorly resistant sedimentary rocks underlie the

landslide debris; resistant volcanic flows (not shown) cap the sedimentary rocks. In many areas where poorly resistant rocks underlie a resistant caprock, conditions for landsliding are favorable. Highly fractured rocks in canyon are schist and gneiss.

FIGURE 47.—ORTHOPHOTOGRAPH AND PERSPECTIVE PHOTOGRAPH OF SAME AREA.

(Left) Part of perspective aerial photograph showing distortions in powerline caused by relief displacement of image points. (Right) Orthophotograph of the same area showing that relief displacement has been eliminated in preparing orthophotograph. Note that the powerline is straight.

Stereoscopic pair

Approximately 1 mile

FIGURE 48.—AREA SHOWING RELATION OF PHOTOGRAPHIC TONE, LAND-USE PATTERN, AND DRAINAGE TO RESIDUAL SOIL, ROCK TYPE, AND GEOLOGIC STRUCTURE (SOUTH CAROLINA).

[Approximate scale 1 : 60,000. Photographs by Army Map Service]

Aerial photographs commonly show an association of features that is meaningful to the interpreter. Here photographic tones, land-use pattern, and drainage pattern are associated with specific soils, rock types, and geologic structure. Note that the small scale of the photographs is a significant factor in showing the striking land-use pattern and drainage pattern (see also fig. 4). The circular land-use pattern of the farmed area generally

bounded by vegetated areas, as at *A*, represents soils developed on underlying mafic rocks. Rocks in the immediately surrounding vegetated areas are largely silicic intrusive types. The drainage characteristics of the area also suggest a pluglike or domal geologic structure. Streams at *B* and *C* form a conspicuous annular pattern around the area of mafic rocks and probably mark the contact of the mafic rock body.

Stereoscopic pair

Approximately 1 mile

FIGURE 49.—SHALE AND THIN SANDSTONE INTERBEDS CAPPED BY POORLY CONSOLIDATED GRAVEL AND SAND, LOCALLY CEMENTED WITH CALCAREOUS MATERIAL (TEXAS).

[Approximate scale 1 : 63,360. Photographs by Army Map Service]

Lack of surface drainage at *A* indicates high degree of permeability in capping material. Note in contrast the striking fine-textured drainage on the relatively impermeable shale area, *B*. Broad depressions, *C*, in capping gravel and sand are very shallow and show little relief even with vertical exaggeration found in the stereoscopic model. These depressions resulted in large part from wind action; some solution of local calcareous cementing

material also may have taken place. Dark areas within depressions represent a darker vegetation growth; light-toned areas represent in part washed-in fine materials that were dry and hence light colored at the time the photographs were taken. Locally some light-toned evaporite deposits may be present.

Stereoscopic pair

Approximately 1 mile

FIGURE 50.—RECENTLY FAULTED STRAND LINES OF FORMER LAKE (NEVADA).

[Approximate scale 1:20,000. Photographs by Soil Conservation Service]

Strand lines of beach sand, *A*, are shown strikingly by dark photographic tone and slightly higher altitudes than surrounding surficial material. Note that strand lines are truncated by a recent fault, *B*, shown by narrow band of dark vegetation and by low scarp. Drainage density is relatively high

on the thin alluvial cover, *C*, but decreases noticeably on opposite side, *D*, of fault where better drained, thicker deposits of alluvial material are present. Strand line is faulted up about 25 feet at *E* by recent fault movement. An irregular fault trace is also seen at *F*.

Stereoscopic pair

Approximately 1 mile

FIGURE 51.—STEEPLY DIPPING SEDIMENTARY ROCKS INTRUDED BY QUARTZ DIORITE (CALIFORNIA).

[Approximate scale 1:20,000. Photographs by U.S. Geological Survey]

Generally massive dark-toned conglomerate sequence, *A*, exhibits coarse-textured drainage and erosional characteristics, whereas fine-grained weakly foliated quartz diorite, *B*, has a fine-textured drainage and erosional topography. Widely spaced joints, conspicuous in many intrusive masses, are not present in the quartz diorite. Dendritic drainage in the conglomerate se-

quence is not typical of most dipping sedimentary rocks; the dendritic drainage pattern suggests a massive character and uniformity of the conglomerate sequence and general lack of bedding which might control the drainage. Local light-toned interbeds, *C*, indicate strike and dip of the sedimentary rock sequence.

Stereoscopic pair

Approximately 1 mile

FIGURE 52.—AREA SHOWING DRAINAGE CHARACTERISTICS IN SURFICIAL MATERIALS (WYOMING).

[Approximate scale 1:28,000. Photographs by U.S. Geological Survey]

Strong contrast in drainage densities of areas *A* and *B* reflect differences in underlying materials. Fine-grained surficial sedimentary deposits, *A*, that form a thin cover on impermeable shale here exhibit fine-textured drainage. The many drainage rills flowing across the fine-grained surficial material

disappear into sand dune area, *B*, which is composed of granular material of high permeability. Although partly stabilized and covered by vegetation the sand dunes locally show barchan shapes, which aid in their identification.

Stereoscopic pair

Approximately 1 mile

FIGURE 53.—AREA OF BASALT FLOWS (IDAHO).

[Approximate scale 1 : 20,000. Photographs by Commodity Stabilization Service]

Conspicuous "snakeskin" pattern is commonly found on the undissected basalt flows, *A*; it is not observed on other rock types in this area. The pattern consists of white or light-toned spots scattered in a dark field. Note that a rounded "shape" is a distinctive part of the pattern. The light-toned rounded areas are mounds of clay and silt 20 feet or more across and 2 or 3 feet high. Grass grows on these areas and causes the light photographic

tone; the basalt is typically barren or covered with sagebrush and has a dark photographic tone. The striped pattern of closely spaced drainage rills, *B*, is also typical of basalt talus slopes in this area; however, similar-appearing stripes are found on a variety of rock types in other areas (see fig. 40). Where basalt cappings are underlain by poorly resistant rocks, conditions are favorable for landslides, as at *C*.

FIGURE 54.—RING-DIKE AREA (NORTH CAROLINA).

[Approximate scale 1 : 58,000. Photographs by Army Map Service]

Ring dike about 1 mile wide and an area of gabbro-diorite within the ring dike can be differentiated from surrounding areas primarily on the basis of the lesser tree coverage and greater land use within the ring-dike area. A ring structure is also suggested by the concentric pattern of trees, A, which may reflect structure within the igneous rocks. The contact of

syenite of the ring dike and gabbro-diorite of surrounding areas cannot be identified in the stereoscopic model, and aerial photographs of this terrain serve primarily to differentiate anomalous features which then must be examined in the field. Note excavation in syenite of the ring dike.

FIGURE 55.—AREA IN MAINE SHOWING ESKER LANDFORM ON PHOTOGRAPHS OF TWO DIFFERENT SCALES.

[A: Approximate scale 1:70,000. Photographs by Army Map Service]
[B: Approximate scale 1:44,000. Photographs by U.S. Geological Survey]

The serpentine shape in plan view and local topographic relief of the esker are readily distinguished in the stereoscopic view of figure A. The esker ridge is discontinuous, but the various segments are clearly part of the same ridge. The association of isolated ridge segments is readily made when small-scale photographs showing a large area are viewed. Landform is the primary recognition feature of esker ridges. In figure B the esker landform is not as readily identified as

in figure A, and on commonly available 1:20,000-scale photographs the serpentine shape would probably not be seen in any one stereoscopic model. Esker sands and gravels are commonly well drained and are a source of borrow material for the construction engineer. Note old secondary road, *a*, built along the top of the esker, probably because of good subgrade and drainage.

Stereoscopic pair

Approximately 1 mile

FIGURE 56.—STABILIZED SAND DUNES (CENTRAL ALASKA).

[Approximate scale 1 : 40,000. Photographs by U.S. Air Force]

Strong contrasts in photographic tone and photographic texture mark sand dunes and interdune areas. Dunes, as at A, are now stabilized and covered with trees. Coarse well-drained sands of the dunes support dark-toned black spruce. Light-toned interdune areas of frozen silt support grasses. Lakes were formed on the original glacial outwash plain, which

was the source of sand for dune formation. The shape of the dune landform is an important aid to recognition, and the association of trees is significant in the interpretation of the soils and ground conditions. Relief of the dunes is vertically exaggerated in the stereoscopic model.

Stereoscopic pair

Approximately 1 mile

FIGURE 57.—MORAINAL DEPOSITS OF TWO GLACIATIONS (CENTRAL ALASKA).

[Approximate scale 1 : 40,000. Photographs by U.S. Air Force]

Arcuate plan-view shape of terminal moraine, *A*, is marked by a lighter photographic tone than that of the surrounding area. This moraine is characterized by an abundance of small undrained lakes and ponds and by poorly integrated drainage. In older terminal moraine, *B*, lakes and ponds

are largely drained, but arcuate plan of this moraine is still preserved. Terminal moraine, *C*, represents an advance only slightly younger than *A*. Note similarity of topographic expression and development of ponds and lakes in moraines *A* and *C*.

Stereoscopic pair

Approximately 1 mile

FIGURE 58.—MORAINAL DEPOSITS OF CONTINENTAL GLACIATION (SOUTH DAKOTA).

[Approximate scale 1 : 60,000. Photographs by Army Map Service]

Terminal moraine, *A*, contains generally few lakes and ponds in contrast with older ground moraine, *B*, in which water-filled kettle holes are numerous. Arcuate plan-view shape and higher relief than surrounding ground moraine are typical of the terminal moraine. Note drainage rills developed on parts of topographically high terminal moraine, but general lack of well-

developed surface drainage in ground-moraine areas. Ponding also indicates poor drainage in this area. Linear trends parallel to arcuate border of terminal moraine—which represent depositional and erosional characteristics—are similar to some linear trends indicative of faults in other areas.

Stereoscopic pair

Approximately 1 mile

FIGURE 59.—GENTLY DIPPING SEDIMENTARY ROCKS LYING UNCONFORMABLY ON GNEISS-GRANITE-SCHIST COMPLEX (UTAH).

[Approximate scale 1:20,000. Photographs by U.S. Geological Survey]

Strong photographic tone differences mark the gneiss-granite-schist area, *A*, and the sedimentary rocks, *B*. Relatively even dip-slope surfaces of sedimentary rocks contrast strongly with hummocky erosional topography of underlying crystalline rocks. The fine-textured dendritic drainage on the crystalline rocks stands out, although such fine-textured drainage is not necessarily diagnostic or typical of igneous and metamorphic areas. The gneiss-granite-schist area shows no bedding, but bedding is marked in the overly-

ing sedimentary rocks by topographic breaks in slope. Light photographic tone and vertical cliffs are characteristic of thick sandstone formation in this area. Large talus blocks, at base of slope, *C*, indicate massive and resistant character of overlying rocks. Shale and silty shale unit below sandstone has a lesser angle of slope, but this slope is masked in part by debris from overlying sandstone.

Stereoscopic pair

Approximately 1 mile

FIGURE 60.—GENTLY DIPPING SEDIMENTARY ROCKS CUT BY NUMEROUS NEAR-VERTICAL FAULTS (UTAH).

[Approximate scale 1:63,360. Photographs by Army Map Service]

Sedimentary rocks are indicated particularly by topographic expression. Jointed, resistant sandstone beds stand in bold cliffs, *A*. Soft rocks have lesser angles of slope. Strong photographic tone differences mark contacts of some rock units, as at *B*; locally vegetation changes are suggestive of different rock types, *C*.

Lava flow, *D*, cuts discordantly across formational contacts. Remnant

lava flow at *E* appears to have been continuous with flow at *D*. Small cinder cone, *F*, demonstrates use of shape as a recognition element of constructional landforms.

Faults are commonly marked by conspicuous topographic alignments (*G*, *H*). Throw on fault *G* is about 100 feet; on *H* the throw is about 150 feet. Note narrow alignments of vegetation marking faults, *K*.

Stereoscopic pair

Approximately 1 mile

FIGURE 61.—FLAT-LYING BEDS OF SANDSTONE, LIMESTONE, AND SHALE (TEXAS).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Limestone caprock, *A*, shows a concentration of oak trees along rim but not across capping bench, which is covered by a veneer of cherty conglomerate. Sandstone break at *B* also has oak trees. Certain oaks have an affinity for limestone soils and some for sandy soils, but oak types are not distinguishable on conventional black-and-white photographs at a scale of

1:20,000. Shale valleys are covered with mesquite and locally have stock tanks, *C*, which suggest underlying impermeable materials. Note dendritic drainage and distribution of vegetation bands along the topographic contour, which in places form closed loops and suggest flat-lying or nearly flat-lying beds.

Stereoscopic pair

Approximately 1 mile

FIGURE 62.—AREA OF FAULTED, GENTLY DIPPING SEDIMENTARY ROCKS (UTAH).

[Approximate scale 1:37,000. Photographs by U.S. Geological Survey]

Strong contrasts in drainage densities and in erosional features of the terrain result from different sedimentary rock types. Coarse-textured drainage of little-dissected area, *A*, marks a persistent limestone bed that locally forms bluffs. These bluffs overlie fine-grained sandstone and shale, *B*, which have a lesser angle of slope than the limestone, although the difference in slope angle is masked by the vertical exaggeration of the stereoscopic model. Note that top of limestone and topographic surface coincide permitting ready

estimate of the amount of dip. Dark-toned shale and fine-grained sandstone and sandy shale at *C* show fine-textured drainage and erosional topography. Note closely spaced joints in fine-grained sandstone beds at *D*. Vertical offsets of resistant limestone bed at *E* are conspicuous. Drainage along trace of faults is prominent at *F* and *G*. A lower sandstone, *H*, contrasts locally with overlying dark sandstone and shale as a result of its light photographic tone and cover of scattered small trees.

Stereoscopic pair

Approximately 1 mile

FIGURE 63.—SHALE IN SEMIARID CLIMATIC AREA (UTAH).

[Approximate scale 1 : 20,000. Photographs by U.S. Geological Survey]

Fine-textured drainage is typical of shale and other fine-grained clastic rock types. Relief is commonly subdued and divide areas gently rounded. Note that rounding of some divide areas may not be conspicuous because of vertical exaggeration of the stereoscopic model. For example, the relief

at *B* is only about 70 feet. The fine-textured drainage and erosional topography suggest plastic soils. The numerous angular crenulations in minor tributaries probably reflect closely spaced joints. Thin light-toned bands, *A*, are expressions of bedding.

Stereoscopic pair

Approximately 1 mile

FIGURE 64.—SHALE AND LIMESTONE IN HUMID CLIMATIC AREA (VIRGINIA).

[Approximate scale 1:43,000. Photographs by U.S. Geological Survey]

Gently dipping shale, *A*, shows a fine-textured drainage. Main streams draining shale flow almost directly in the downdip direction. Limestone underlies anticlinal ridge, *B*. Sinkholes are present locally, *C*, but are not conspicuous within the area. In general the limestone areas are less dissected than shale areas because of better internal drainage in limestone.

Valley, *D*, is underlain by shale. Note discordance of strike of steeply dipping beds, *E*, with scarp, *F*, which suggests presence of a fault along this topographic break in slope. Thin resistant bed of sandstone, *G*, crops out conspicuously on flank of anticlinal ridge. Trellis drainage in area *D* is typical of folded sedimentary rocks.

Stereoscopic pair

Approximately 1 mile

FIGURE 65.—AREA OF GENTLY DIPPING LIMESTONE AND SHALE (PENNSYLVANIA).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Impermeable shale, *A*, has a greater resistance to erosion than the limestone, *B*, and stands topographically high in this area. The contact of shale and limestone is marked by a pronounced topographic break, as at *C*. The shale has been noticeably dissected by stream erosion in contrast to the limestone in which drainage is in large part internal. Note orchards in well-drained limestone areas. Vegetation along stream valleys in the shale

accentuates the drainage contrast of shale and limestone areas. Soil mottling, *D*, in limestone areas occurs where soil cover is thin and allows differences in moisture conditions, believed to result from drainage channels in the limestone bedrock, to stand out. Despite good drainage in the limestone area residual soils developed on limestone may react to engineering tests as a plastic soil and not as a granular soil. Limestone quarry is at *E*.

Stereoscopic pair

Approximately 1 mile

FIGURE 66.—AREA MANTLED BY GLACIAL DEPOSITS (SOUTH DAKOTA).

[Approximate scale 1 : 60,000. Photographs by Army Map Service]

Topographically high area, *A*, with typical knob-and-kettle topography is covered by morainal material; ponds are common but surface drainage channels are conspicuously absent. Rim of high ground has been noticeably dissected by deep channels. The distribution of these channels, accentuated by dark-toned vegetation, forms a radial pattern similar to that over some sub-

surface structures in other areas. Drainage disappears in permeable material, *B*, surrounding the high area. Contrast lack of surface drainage rills in moraine at *A*, where drainage is poor, as indicated by ponds, with lack of surface drainage rills in outwash at *B*, where internal drainage is good. Well-drained area, *C*, probably also represents glacial outwash.

Stereoscopic pair

Approximately 1 mile

FIGURE 67.—GLACIATED AREA IN SOUTHEASTERN ALASKA.

[Approximate scale 1 : 40,000. Photographs by U.S. Navy]

Conspicuous linear trends, *A*, represent glacial grooving. These lineations, except for the fanning out in the direction of ice movement, may appear on photographs similar to lineations that represent foliation in metamorphic rocks. Drumlinoid features that give rise to this linear pattern are generally found in broad, flat, and topographically low areas, such as the floors of broad valleys. Commonly the drumlinoid features are elongated parallel or

subparallel to the valley or general topographic grain. Lineations representing foliation on the other hand may transect or parallel the topographic grain; unlike drumlinoid features they are not restricted to any one topographic level. Pock-marked area, *B*, is glacial outwash and probably some glacial lake deposits.

Stereoscopic pair

Approximately 1 mile

FIGURE 68.—APPROXIMATELY FLAT-LYING LIMESTONE AND INTERBEDDED SANDSTONE AND MARLSTONE BEDS COVERED LOCALLY BY ALLUVIUM AND WINDBLOWN DEPOSITS (TEXAS).

[Approximate scale 1 : 63,360. Photographs by Army Map Service]

Rounded dark-toned depressions are sink holes that mark area of limestone. Drainage is primarily internal and few surface drainage channels may be seen; a few short surface rills drain into the sink holes, as at *A*.

In contrast to the limestone area, surface drainage is conspicuously developed in the interbedded sandstone and marlstone, *B*, but becomes less well developed in permeable alluvium and windblown deposits, *C*.

Stereoscopic pair

Approximately 1 mile

FIGURE 69.—AREA OF BASALT FLOWS (IDAHO).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

The oldest basalt, *A*, shows subdued rounded topography and well-developed surface drainage. A younger basalt, *B*, is interbedded with light-toned sedimentary rocks. Some surface drainage has developed on the sedimentary rocks. The youngest basalt, *C*, shows a "lizard skin" appearance on

aerial photographs; locally a collapse structure may be present as at *D*. Almost no integrated surface drainage is present on the youngest basalt. Stream *E* flows in a fault valley. The fault is younger than, and separates, basalts *A* and *B*; basalt *A* has been upthrown.

Stereoscopic pair

Approximately 1 mile

FIGURE 70.—AREA OF GRANITE (SOUTH DAKOTA).

[Approximate scale 1:24,000. Photographs by U.S. Geological Survey]

Dendritic drainage, seen best in stereoscopic view, is typical of many terrains underlain by intrusive igneous rocks or other generally homogeneous rocks. The irregularly spaced joints in several different orientations are characteristic of granite and other intrusive rocks; extremely irregular topog-

raphy is also common in such terrain. Banding, suggestive of sedimentary or metamorphic rocks, is absent. The occurrence of trees predominantly of one variety and the lack of conspicuous preferred orientation of vegetation is suggestive of uniform composition of bedrock.

Stereoscopic pair

Approximately 1 mile

FIGURE 71.—AREA OF GRANITIC INTRUSIVE ROCKS (WYOMING).

[Approximate scale 1:28,000. Photographs by U.S. Geological Survey]

Profuse, irregularly spaced joints in several different orientations are typical, although not necessarily diagnostic, of intrusive igneous rocks. The massive character of the rocks and apparent lack of bedding in turn suggest igneous intrusive rocks, although locally the rocks shown appear similar to some highly fractured massive sandstone. Conspicuous rectilinear depres-

sions, as at *A*, marked by dark-toned vegetation, are shear zones that are more easily eroded than surrounding rock areas, and probably have a higher concentration of moisture that supports vegetation growth. In places, as at *B*, older shear zones have been offset by younger fractures. Note strong control of drainage by faults and joints.

Stereoscopic pair

Approximately 1 mile

FIGURE 72.—AREA SHOWING VEGETATION DIFFERENCES IN IGNEOUS-METAMORPHIC TERRAIN
(SOUTHEASTERN ALASKA).

[Approximate scale 1 : 40,000. Photographs by U.S. Navy]

Dense stand of coniferous trees, *A*, is typical of massive marble and related carbonate rocks in this area. Diorite, *B*, has only patchy tree growth but shows typical crisscross joint pattern of short lineations common in many intrusive rocks. Area *C* is schist. The surface expression of the schist is

similar to that of the diorite in patchy tree cover and irregular topography but the schist has a dominant lineation direction not present in the intrusive rocks. Vegetation bands, *D*, may cover thin beds of marble. Note that gently curved vegetation bands suggest steeply dipping rock units.

Stereoscopic pair

Approximately 1 mile

FIGURE 73.—AREA UNDERLAIN BY SILICIC VOLCANIC TUFFS AND FLOWS AND BEDDED ARGILLITE OR SLATE (NORTH CAROLINA).

[Approximate scale 1 : 58,000. Photographs by Army Map Service]

Major streams, 4, are developed along the regional cross-joint direction. Roads extending generally parallel to the major streams accentuate the cross-joint direction. Minor tributary streams flow predominantly parallel to the regional structural trend and at right angles to the cross joints. Hills are commonly elongate in the direction of the regional strike, which may represent foliation or flow cleavage rather than bedding. In such low-

relief areas the extensive land-use pattern tends to obscure structural trends; commonly the structural trends can be better observed from a mosaic composed of several photographs. Any one stereoscopic pair can only show a small part of the regional geologic structure. Structural interpretation may also be facilitated by study of separate drainage maps, as in figure 8.

Stereoscopic pair

Approximately 1 mile

FIGURE 74.—AREA OF FOLDED, FAULTED, AND HIGHLY METAMORPHOSED ROCKS (NORTH CAROLINA).

[Approximate scale 1 : 57,000. Photographs by Army Map Service]

This pair of photographs illustrates a use of drainage characteristics in the interpretation of geologic structure. Where dips are gentle, tributary streams developed on the updip side of a strike valley commonly will be longer than tributary streams developed on the downdip side of the valley, as at *A*. The direction of dip of strata is thus indicated. Length relations of streams are commonly best studied on a separate drainage overlay (see fig. 7) where vegetation and other obscuring features in the stereoscopic model are not present. In the area shown, a plunging fold is also suggested by the

distribution of photographic tones and gentle curvature of streams around the nose, *B*, of the fold. Arrow indicates direction of plunge. Many streams in highly metamorphosed terrain have developed in response to, and therefore reflect, the strike and dip of foliation rather than bedding. Prominent cross joints are expressed by linear segments of major streams, as at *C*, and by alinement of vegetation along some tributary streams. Note conspicuous fault indicated by alinement of stream segments, *D*; this fault is inconspicuous on the ground.

Stereoscopic pair

Approximately 1 mile

FIGURE 75.—AREA UNDERLAIN BY PHYLLITE AND SLIGHTLY METAMORPHOSED SLATY ROCKS (ALABAMA).

[Approximate scale 1:29,000. Photographs by U.S. Geological Survey]

Poorly resistant phyllite and slightly metamorphosed slaty rocks here are characterized by fine-textured drainage, commonly found in fine-grained clastic rocks. The area also has a fine-textured erosional topography. Several conspicuous linear trends, *A*, are at right angles to the regional strike of bedding. These trends probably represent regional cross joints. In areas of metamorphic rocks the prominent regional cross joints commonly are widely

spaced and streams flow along them. The linear trend of the stream at *B* is parallel to the regional strike of bedding. There is no direct surface manifestation of bedding. Headwater tributaries form a generally dendritic drainage pattern that suggests uniformity of rock type, but principal streams show rectangular drainage probably influenced by bedding and cross joints.

Stereoscopic pair

Approximately 1 mile

FIGURE 76.—HEAVILY VEGETATED TERRAIN UNDERLAIN BY METAMORPHIC AND EXTRUSIVE VOLCANIC ROCKS (SOUTHEASTERN ALASKA).

[Approximate scale 1 : 40,000. Photographs by U.S. Geological Survey]

Numerous subparallel lineations, *A*, represented primarily by rectilinear depressions that channel the drainage, are expressions of foliation in the metamorphic rocks. Conspicuous rectilinear depressions, *B*, transecting the foliation direction, represent faults. The remnant of a recent volcanic cone,

C, is recognized by its shape. Note lobate patterns of vegetation, *D*, suggesting areas of flow rocks. Absence of lineations in area *E* suggests that flows also are present there.

Stereoscopic pair

Approximately 1 mile

FIGURE 77.—FLAT-LYING BEDS OF LIMESTONE AND SHALE (KANSAS).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Strong contrasts in photographic tone result primarily from different lithologic characteristics of underlying formations; dark-toned beds are shale with some grassy vegetation; light-toned beds are limestone. The near-coincidence of bedding traces and topographic contours, closed loops of tonal patterns, as well as the dendritic drainage pattern are typical of flat-lying beds. Small thickness of limestone interbeds is not conducive to development of

sink holes. In some places individual limestone beds can be distinguished on the basis of weathering and erosional characteristics; massive cherty limestone benches may show rounded rims, whereas thin platy limestone benches may show a sharp break at the rim. Abundant trees and shrubs along part of bed A suggest a plentiful supply of water. Bed A is locally an aquifer.

Stereoscopic pair

Approximately 1 mile

FIGURE 78.—FLAT-LYING BEDS OF SANDSTONE, LIMESTONE, AND SHALE (TEXAS).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Flat-lying beds are indicated by benchlike landform, extension of tonal bands along topographic contour, and by dendritic drainage. Dark photographic tone on sandstone caprock, *A*, results from growth of oak trees. Benches of limestone, *B*, exhibit concentration of oak growth along rims but

not across flats. Valley areas are underlain by shale, which is covered predominantly by mesquite growth. Stock tanks, *C*, are common in impermeable material and where present suggest shale in this region.

Stereoscopic pair

Approximately 1 mile

FIGURE 79.—AREA OF SPARSE OUTCROPS UNDERLAIN LARGELY BY GENTLY FOLDED SANDSTONE,
CONGLOMERATE, AND SHALE (NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

Dip slopes are characterized by few streams in contrast to back slopes on which a system of numerous subparallel streams has developed. Drainage in the dip-slope direction is generally coarse textured except for profuse channels developed at heads of tributaries. Drainage on the back slopes is fine textured. The textural difference, or drainage density difference, rather

than any specific drainage pattern, stands out. The back slope, with its fine-textured drainage, is predominantly a shale section in contrast to the sandstone and conglomerate of the dip slope. Note horizontal offset of light-toned sandstone beds by near-vertical faults, illustrated at A, transverse to the strike.

Stereoscopic triplet

Approximately 1 mile

FIGURE 80.—GENTLY TO STEEPLY DIPPING SEDIMENTARY ROCKS OVERLYING SCHIST-GNEISS-GRANITE
COMPLEX (WYOMING).

[Approximate scale 1:59,000. Photographs by Army Map Service]

Striking discordance in dip of beds can be seen between beds at *A* and *B* and between near-vertical beds at *C* and flat-lying beds at *D*. Such a discordance in dip may represent tightly folded structures in some areas but here it represents faulting. Note also the conspicuous discordance in strike between beds at *A* and *C* and between beds at *B* and *C*. The locations of fault traces may be inferred from the positions of discordant beds, but

details of fault structure and positions of formation contacts cannot be seen clearly on the photographs of many parts of this complex area. Dark-toned rocks, *E*, lacking bedding or banding are schist-gneiss-granite complex. Light-toned jointed rocks, *F*, are predominantly limestone and dolomite. Where light-toned rocks are cut by a stream, as at *G*, the outcrop pattern forms a V in the direction of dip.

Stereoscopic pair

Approximately 1 mile

FIGURE 81.—GENTLY FOLDED SEDIMENTARY ROCKS (CENTRAL UTAH).

[Approximate scale 1 : 20,000. Photographs by Soil Conservation Service]

Contrasting photographic tones, representing different soil and rock types, strongly outline plunging anticline. Plunge of anticline is also indicated by stream curvature at *A* and *B*. Note that major stream has generally consistent direction of flow until it reaches anticlinal nose at *C*, at which point it is deflected in the direction of plunge of the structure. Outcrop pattern

of contact between light- and dark-toned rocks, *D*, along flank of the anticline forms pronounced V's, which point in the direction of dip. Local intrusions of basalt dikes, *E*, stand in topographic relief above softer surrounding rocks.

FIGURE 82.—RING DIKE IN NEW HAMPSHIRE.

[Approximate scale 1:34,000. Photographs by U.S. Geological Survey]

The ring dike, composed of several types of igneous rock, is the most conspicuous feature of the terrain. Different rock types in places are reflected in the topographic expression of terrain. An outer ring and partial inner ring, *A*, composed of monzonite stand in conspicuous topographic relief. Hornblende diorite, in places foliated, forms the low areas, *B*. Some geologic

contacts may be located on the basis of topography. However, specific placement of contacts cannot be made from the stereoscopic model; but in igneous terrain, where one rock type may grade into another, contacts are difficult to select in the field. The ring dike is cut by several faults, *C*, indicated by alinements of scarps, depressions, and vegetation.

FIGURE 83.—GENTLY DIPPING SEDIMENTARY ROCKS OFFSET BY NEAR-VERTICAL FAULT (UTAH).

[Approximate scale 1 : 20,000. Photographs by U.S. Geological Survey]

Line separating areas of contrasting photographic tones is trace of fault. The straightness of the fault trace indicates that the fault has approximately a vertical dip. Note vertical offset of dark-toned shale bed, *A*, and difference in erosional character of topography on opposite sides of fault at *B*. Faint trace of fault in alluvium at *C* is locally marked by differences in

drainage on opposite sides of the fault. Light-toned sandstone interbeds, *D*, cap local areas and exhibit serrated margins as a result of closely spaced joints. Fine-textured drainage is typical of the poorly resistant shale and thin sandstone interbeds.

FIGURE 84.—FAULTED, GENTLY DIPPING SEDIMENTARY ROCKS (UTAH).

[Approximate scale 1:20,000. Photographs by U.S. Geological Survey]

Conspicuous high-angle faults offset beds in many places, as at *A*, where limestone caprock is down-faulted about 125 feet. Note the effect of vertical exaggeration in the stereoscopic model on the amount of offset. Fault is indicated by scarp, *B*, and its alinement with stream at *C*. Note right-angle bend in stream at *D* along trace of fault. Another fault is indi-

cated by alinement of stream *E* and break in vegetation *F*. Several other faults with only small displacements are shown by alinements at *G*. Resistant limestone caprock stands in vertical bluffs overlying less resistant shale and shaly siltstone that have a lesser angle of slope.

Stereoscopic pair

Approximately 1 mile

FIGURE 85.—VEGETATED TERRAIN UNDERLAIN BY IGNEOUS AND METAMORPHIC ROCKS LOCALLY COVERED BY BASALT FLOWS (SOUTHEASTERN ALASKA).

[Approximate scale 1:40,000. Photographs by U.S. Navy]

A significant contrast between the igneous and metamorphic complex and younger volcanic flows is shown in the distribution of faults and vegetation. Faults, indicated primarily by rectilinear depressions, *A*, are common in the igneous and metamorphic rocks, but are absent from the area of lava flows, *B*. Note that certain faults, as at *C*, may be traced up to the lava flows and that continuations of these faults may be picked up on the opposite side of the flow area. Some of the shorter lineations, as at *D*, probably represent wide-spaced joints. Lobate patterns of dark-toned vegetation, *E*, commonly

delineate the edges of individual lava flows. Small cone at *F* is suggested by shape of constructional landform. Relatively flat, muskeg-covered flows are generally poorly drained and locally contain numerous shallow ponds, *G*, that lack any integrated drainage. The muskeg areas have a relatively light photographic tone because of the mossy vegetation and do not appear dark despite the abundance of moisture. The photographic texture of the muskeg areas is also distinctive.

Stereoscopic pair

Approximately 1 mile

FIGURE 86.—AREA OF CRYSTALLINE ROCKS (WYOMING).

[Approximate scale 1 : 60,000. Photographs by Army Map Service]

Numerous widely spaced joints, typical of many intrusive masses, are conspicuous, although widely varying orientations of joints, found in most plutonic rocks, are not prominent. Drainage is markedly controlled by faults and joints; the dendritic drainage that is normally characteristic of crystalline masses is thus subdued. Although the rocks shown here are locally

gneissic, evidence of bedding of original sediments or gneissic structure is generally lacking. Major fault, *A*, marked by stream alinement, is offset by younger fault, *B*, also delineated by stream alinement. Note alinement of streams on opposite side of divide, *C*.

Stereoscopic pair

Approximately 1 mile

FIGURE 87.—LAVA FLOW LYING UNCONFORMABLY ON GENTLY DIPPING SEDIMENTARY ROCKS (NEW MEXICO).

[Approximate scale 1 : 54,000. Photographs by Army Map Service]

Resistant sandstone beds, *A*, dipping 15° are truncated by overlying lava flow, *B*. Bedding stands out where topographic and bedding surfaces coincide. Hogback landform is also prominent where resistant sandstone beds and intervening shale areas have been etched by erosion. Note how vertical exaggeration of dip causes unconformable relation between sedimentary beds and overlying lava flow to stand out. Surface of lava flow has mottled

appearance that is typical of basalt flows in many areas. Basaltic dikes, *C*, stand in topographic relief above soft shale shown by fine-textured drainage at *D*. Some landsliding has taken place at *E* where resistant lava overlies less resistant rocks. Road alignment *F* is subject to potential destructive action of additional slides.

Stereoscopic pair

Approximately 1 mile

FIGURE 88.—GENTLY DIPPING SEDIMENTARY ROCKS OVERLAIN IN PART BY RIVER GRAVELS (UTAH).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Flat-lying gravel cap, *A*, truncates underlying sedimentary rocks. Traces of bedding below granular material of gravel cap are indicated by minor breaks in slope, *B*, accentuated by shadows. Surface drainage is conspicuously absent from well-drained broad gravel flat, *D*, which represents a

younger, lower and less dissected terrace than *A*. Gullies in silty valley-fill, *E*, exhibit near-vertical slopes where recent stream dissection has taken place. Note effect of vertical exaggeration in the stereoscopic model. True dip of beds at *C* is about 6°.

Stereoscopic pair

Approximately 1 mile

FIGURE 89.—GENTLY FOLDED SEDIMENTARY ROCKS IN HEAVILY VEGETATED AREA
(NORTHERN GUATEMALA).

[Approximate scale 1:65,000. Photographs by Army Map Service; published with permission of the Guatemala Government]

Anticlinal structural feature in heavily vegetated jungle area is indicated by erosional characteristics of terrain and by drainage. Core of anticline, *A*, is topographically higher than surrounding area and is somewhat more dissected. Bedding and direction of dip are suggested by the topographically

high bands of ground at *B*; note that tree crowns appear to fall in a dipping plane. Stream, *C*, has been deflected around the nose of the anticline; the convex side of the curve indicates the direction of plunge, but the major stream of the area has maintained its course across the anticline.

Stereoscopic pair

Approximately 1 mile

FIGURE 90.—PLUNGING ANTICLINE IN GENTLY FOLDED ROCKS (SOUTHERN UTAH).

[Approximate scale 1:37,000. Photographs by U.S. Geological Survey]

Distribution of rock types and characteristics of drainage clearly outline plunging anticline. Note that major stream curves around nose of the anticline and the convex side of the curve indicates the direction of plunge. Lithologic differences between formations are conspicuously shown by contrasts in photographic tone and erosional characteristics of terrain. Dark-toned formation, *A*, is an interbedded sequence predominantly of red sandstone and some mudstone and shale. Light-toned formation, *B*, is made up of a rather uniform weakly cemented massively bedded sandstone showing a fine-textured dendritic drainage. Drainage rills in formation *A* and *C* are

controlled in part by hard, resistant sandstone interbeds that locally channel the drainage along the interbeds. Formation *C* largely comprises a series of red to brown silty sandstone and shale. Rocks at *D* include predominantly thin-bedded red sandstone and limestone interbeds. Bedding is prominently shown because topographic surfaces and bedding surfaces coincide in many places. Dip of sedimentary beds is exaggerated as in most stereoscopic models. True dip at *E* is 5°. Dark-toned resistant basalt dike, *F*, stands in relief above light-toned rocks.

Stereoscopic pair

Approximately 1 mile

FIGURE 91.—STRATIGRAPHIC SECTION ACROSS GENTLY FOLDED ANTICLINE (UTAH).

[Approximate scale 1 : 20,000. Photographs by U.S. Geological Survey]

Breaching of anticline by major river has exposed cross section of the fold. Bedding is clearly represented at *A* where bedding surfaces coincide with topographic surfaces. Effect of vertical exaggeration on dip is shown on both flanks of the anticline. True dip at *A* is about 20°; at *B* the beds are horizontal; at *C* the dip is about 4°. Shale, siltstone, and fine-grained sandstone, *D*, exhibit dark photographic tones; relatively closely spaced joints

may be seen locally. Coarse sandstone with some conglomerate, *E*, has light photographic tone; widely spaced joints are present as at *F*. The coarse-grained rocks characteristically form cliffs. Where beds are nearly horizontal the fine-grained rocks have slopes that are less steep than those of the coarse-grained rocks. Where beds are dipping, the softer rocks are in many places etched out by erosion leaving hogbacks of resistant rock types.

Stereoscopic pair

Approximately 1 mile

FIGURE 92.—GENTLY DIPPING SEDIMENTARY ROCKS ON EAST SIDE OF SAN RAFAEL SWELL (UTAH).

[Approximate scale 1:20,000. Photographs by U.S. Geological Survey]

Bedding on flank of fold is clearly shown by photographic tone differences and hogback landform where dip surfaces and topographic surfaces coincide. Note effect of vertical exaggeration on dip in the stereoscopic model; beds at *A* have true dip of 6°. Massive crossbedded sandstone, *B*, has light photographic tone and widely spaced joints oriented predominantly in one direction; locally its appearance on aerial photographs is similar to some

igneous rocks. Dark-toned resistant beds, *A*, are red mudstone and lenticularly bedded medium-grained sandstone. Poorly resistant interbedded red limy sandstone, mudstone, and limestone, *C*, is easily eroded and has fine-textured drainage. Beds at *C* are flat lying. FIGURE 93.—UNCONTROLLED MOSAIC OF UMIAT ANTICLINE AREA, NORTHERN ALASKA, UNDERLAIN BY SHALE, SANDSTONE, CONGLOMERATE, AND GRAYWACKE.

[Photographs by U.S. Navy]

Curvature of streams, A, has developed on flank of anticline where hard and soft interbeds are exposed. Anticline has been breached into soft shale permitting streams developed on the more resistant dip slope to curve along

soft interbeds and not across the axis of the fold. Contrast figure 81 where stream curvature indicates position of structural axis and direction of structural plunge.

Approximately 1 mile

Stereoscopic pair

FIGURE 94.—SUBSURFACE STRUCTURE REFLECTED IN SURFACE DRAINAGE CHARACTERISTICS (TEXAS).

[Approximate scale 1 : 63,360. Photographs by Army Map Service]

Subsurface structures at *A* and *B* are suggested by drainage characteristics of the area. Streams flanking the structure at *A* curve around the structure in their headwater portions. Tributary streams drain radially off the structure (see figures 9 and 95). In addition, the crudely circular pattern of more highly dissected ground and the pattern of dark pho-

tographic tone, *C*, which results from a concentration of vegetation, suggest subsurface structure. Compressed meanders are present over a subsurface structure at *B*. Also note stream deflection downstream from *D* which is a further suggestion of subsurface structure in area *B*.

Approximately 1 mile

Stereoscopic pair

FIGURE 95.—SAME PHOTOGRAPHS AS FIGURE 94, BUT REVERSED TO SHOW PSEUDOSCOPIC EFFECT AS AN AID TO INTERPRETATION.

[Approximate scale 1 : 63,360. Photographs by Army Map Service]

Reversal of the positions of two aerial photographs of a stereoscopic pair produces the well-known pseudoscopic effect, in which stream valleys appear as ridges and hills look like depressions. This unnatural view of the terrain commonly accentuates stream characteristics, which may be significant indicators of subsurface structure, as at 4. The pseudoscopic view also commonly facilitates plotting of drainage.

FIGURE 96.—UNCONTROLLED MOSAIC OF WAINWRIGHT AREA, NORTHWESTERN ALASKA.

[Photographs by U.S. Navy]

The radial-dendritic drainage pattern shown is anomalous to the Arctic coastal plain where northward-flowing streams predominate. Local relief across the area is only a few feet per mile. The radial drainage pattern, suggestive of subsurface structure, is readily seen on the small-scale mosaic but could be easily overlooked on single photographs or individual stereoscopic pairs. Note the northward deflection of the Kugrua River; the abrupt change in direction of streamflow is believed due to subsurface struc-

ture. Seismic work indicates a structural nose plunging southeast in the north-central part of the area. Outcrops are sparse in the area and surface indications of structure, other than drainage pattern, are generally lacking. The drainage pattern of this area is similar to that of an area to the southeast where gas was found in a subsurface structure that had been defined by geophysical methods.

Stereoscopic pair

Approximately 1 mile

FIGURE 97.—AREA UNDERLAIN PREDOMINANTLY BY GENTLY DIPPING SANDSTONE AND SHALE
(NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

Sandstone beds stand out because of photographic tone, relief, and vegetation changes, as at *A*. As these sandstone beds are traced across the area they lose their topographic expression, as at *B*, and are replaced by shale of the underlying formation. The rate of "shaling" or change of facies from sandstone to shale can be calculated from quantitative studies of the aerial

photographs, and the direction of maximum thinning of the sandstone section determined. Note the effect of vertical exaggeration on dip of resistant sandstone beds; true dip is 7° to 8° in this area. Effect of vertical exaggeration is also shown at *C* where minor topographic breaks in slope, accentuated by shadows, reflecting thin resistant beds stand out.

Stereoscopic pair

Approximately 1 mile

FIGURE 98.—GENTLY DIPPING SEDIMENTARY ROCKS CUT BY HIGH-ANGLE FAULTS (NEVADA).

[Approximate scale 1 : 20,000. Photographs by Soil Conservation Service]

Topographic expression of resistant, jointed quartzite bed, *A*, permits differentiation of quartzite and underlying carbonate sequence of rocks, *B*. High-angle faults, transverse to the strike of bedding are shown at *C* and *D* by the vertical offset of the quartzite bed. The contact of quartzite and underlying carbonate rocks is the locus of polymetal sulfide veins, but the veins cannot be seen in the stereoscopic model. Note mine dumps, *E*, mark-

ing location of crosscuts to base of the quartzite, which dips into the slope about 20° to 25°. Direction of dip is clearly indicated by *V* in outcrop pattern of quartzite bed where major stream cuts through the ridge. Trace of a major fault with several thousand feet displacement is only weakly shown parallel to slope at *F* and *G* where density of vegetation is slightly greater on the downhill side of the fault trace.

Stereoscopic pair

Approximately 1 mile

**FIGURE 99.—COMPLEXLY FOLDED AND FAULTED AREA OF GREENSTONE, SCHIST, LIMESTONE AND MARBLE
(SOUTHEASTERN ALASKA).**

[Approximate scale 1:40,000. Photographs by U.S. Navy]

rich gold-quartz veins have been found in this area. Note that fault lineations characteristically are rectilinear depressions.

Stereoscopic pair

Approximately 1 mile

FIGURE 100.—IGNEOUS AND METAMORPHIC TERRAIN (SOUTHEASTERN ALASKA).

[Approximate scale 1:40,000. Photographs by U.S. Navy]

In this area lead and silver deposits are found locally along the contact of intrusive quartz diorite and metamorphic rocks. Smooth slopes, *A*, are underlain by metamorphic rocks. The closely spaced parallel ridges and depressions, *B*, reflect foliation in the metamorphic rocks. Depressions, *C*, probably represent solution cavities in carbonate interbeds. Lineations, *D*,

transecting the foliation direction are believed to be expressions of faults. The uneven surface, *E*, cut by a crisscross of joints is underlain by quartz diorite. This pattern of lines representing joints is typical, but not necessarily diagnostic, of intrusive rocks. The contact of igneous and metamorphic rocks is in the conspicuous saddle between *A* and *E*.

Stereoscopic pair

Approximately 1 mile

FIGURE 101.—GENTLY TILTED AND FAULTED LAVA FLOWS (OREGON).

[Approximate scale 1 : 54,000. Photographs by Army Map Service]

Perched remnants of basaltic lava, *A*, form skeletal dendritic pattern, which suggests that lava filled former stream valleys. In some areas perched lava remnants are known to cover older auriferous stream gravel. Several faults are indicated by alinements of stream segments, vegetation lines, and photographic tone contrasts (see alinement of arrows). Dip on flow surfaces, as at *B*, may be readily estimated or measured from aerial photographs because of the relatively large area examined in a single view, and because of vertical exaggeration of the dip slope. Note that the younger

flow, *A*, has a gentler dip than the older flows, *B* and *C*. Surfaces *B* and *C* may be correlative and separated by a fault in the intervening valley. At point *D* the younger perched lava flows are also faulted, but throw is considerably less than where older lava flows are displaced by the same fault. In some areas faults displace only the older rocks and do not offset the most recent flows. A long period of fault activity is thus suggested. Note that in monoscopic view fault alinements, *E*, accentuated by vegetation, are striking.

©

Stereoscopic pair

Approximately 1 mile

FIGURE 102.—AREA OF PEGMATITE DIKES (SOUTH DAKOTA).

[Approximate scale 1:24,000. Photographs by U.S. Geological Survey]

Pegmatites in the area shown are generally concordant with schistosity and bedding of quartz-mica schist country rock. In many places the pegmatite dikes stand in topographic relief above the surrounding schist, as at A. The massive, jointed character of the larger pegmatite dikes is similar to other intrusive rocks and contrasts with the thin-bedded schistose rocks. Thin pegmatite dikes commonly cannot be distinguished in the aerial pho-

tographs and only general contact areas can be mapped for most of the wide pegmatite dikes because of the vegetation cover. Locally steeply dipping schist also stands in topographic relief; these rocks can be distinguished by the sheeted character of the outcrops. General structural trends are reflected in topographic expression of parallel ridges and in photographic tones of vegetation in fields, B. Note mining activity in pegmatite at C.

Stereoscopic pair

Approximately 1 mile

FIGURE 103.—METAMORPHOSED SEDIMENTARY ROCKS INTRUDED BY QUARTZ MONZONITE (CALIFORNIA).

[Approximate scale 1 : 47,000. Photographs by U.S. Geological Survey]

Metamorphic rocks here are generally dark toned, as at *A*, and locally show prominent banding; joints are closely spaced and are not conspicuously shown on the photographs. Quartz monzonite, *B*, is relatively light toned and lacks banding, but like most intrusive igneous rocks it has a strong development of irregularly and widely spaced joints that are readily seen in the stereoscopic model. Light-toned streaked, prominent talus slopes, *C*, have

formed where the fine-grained metamorphic rocks are present. In areas of igneous rocks the talus slopes are less well developed; locally large individual talus blocks can be observed at the bases of slopes. A fault trace is suggested by conspicuous linear feature, *D*. Note alinement of short straight linear segments, *E*, on opposite sides of divide; these linear traces may represent the trace of a fault or the prominent development of joints.

FIGURE 104.—DISTINCTIVE LANDFORM OF GRAVEL TERRACES ALONG A MAJOR STREAM
(NORTHEASTERN UTAH).

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

The steplike landform of terraces is conspicuous. Other elements of the soil pattern—vegetation, drainage, and erosional characteristics—provide significant information to the photointerpreter. Absence of surface drainage, as at *A*, suggests well-drained materials. At *A* the material is composed of coarse bouldery gravel that has good internal drainage. Vegetation, *B*, is prominent along edges of upper terrace gravel cap where water emerges from

the gravel. Lower terraces, as at *C*, are more continuous and less dissected than the older terraces at higher altitudes, although recent streams in conspicuous V-shaped gullies, *D*, dissect the edge of the terrace. Terrace deposits commonly are favorable reservoirs for ground-water storage; in addition they provide a ready source of some materials used by the construction engineer.

FIGURE 105.—AREAS SHOWING DRAINAGE CHARACTERISTICS IN SURFICIAL MATERIAL THAT IS PREDOMINANTLY LOESS.

[Approximate scale 1:20,000. Photographs by Commodity Stabilization Service]

Figure A. Contrasting drainage characteristics and differences in photographic tones in areas *a* and *b* suggest differences in character of the surficial materials. The modified dendritic drainage and scoop-shaped valley heads are typical of dissected loess areas, *a*. Lack of surface drainage rills is a feature of sand dune areas, *b*, where materials are coarse-grained, highly permeable, and drainage is largely internal. Note light-and-dark mottled soils in sand dune area. The fine-grain size of loess is believed responsible for the fine-textured drainage (Iowa).

Figure B. As in area shown in figure A, the dissected loess hills exhibit a modified dendritic drainage pattern. Recent erosion has cut deep narrow and sharply defined channels in

the bottoms of broad valleys, as at *a*. Gully walls are essentially vertical. Note characteristic scoop shape of side drainage and serrated ridges along some divides. Light streaks due to thin grass cover or to cultivation are typical of many loess areas. Broad, flat river flood plain, *b*, has good internal drainage and exhibits a lack of visible surface drainage channels (Nebraska).

Figure C. Deeply dissected loess hills have drainage pattern similar to areas shown in figures A and B, but erosion may have proceeded more rapidly than in other areas. Valley walls are sharply defined. Steep valley walls commonly characterize loess (Nebraska).

Stereoscopic pair

Approximately 1 mile

FIGURE 106.—AREA OF SURFICIAL DEPOSITS, PRIMARILY WINDBLOWN (CENTRAL NEBRASKA).

[Approximate scale 1 : 67,000. Photographs by Army Map Service]

Highly dissected loess hills, *A*, abut against well-drained alluvial terraces, *B*. Extensive dissection of loess has resulted in a fine texture of erosional topography and fine-textured drainage. Bottoms of many valleys in loess are notched by recent stream dissection. The modified dendritic drainage pattern is typical of loess area. Note absence of surface drainage rills in terrace alluvium, *B*, and elongate windblown sand hills, *C*, indicating the highly

permeable nature of the underlying materials. Loess is generally considered well drained internally and is thus an exception to the general association of fine-textured drainage and impermeable soils. The fine-textured drainage in loess is believed to be a result of the fine grain size. Contrast appearance here of drainage density in loess with drainage density on large-scale photographs of figure 105.

Stereoscopic pair

Approximately 1 mile

FIGURE 107.—MOTTLED SOILS OF DRIFT PLAIN (IOWA).

[Approximate scale 1:27,000. Photographs by U.S. Geological Survey]

Light-toned areas are generally slightly higher than surrounding dark-toned areas. High areas of light photographic tone are somewhat better drained than the intervening dark areas, and generally contain silty soils with a lesser accumulation of organic material than the depressions. Clay materials and humus have accumulated in depressions to impart dark pho-

tographic tone. Linear pattern of light-toned areas may represent minor recessional moraines. They trend across the direction of movement of ice. Near major streams the reworked glacial drift may be better sorted and locally an important source of borrow material for the construction engineer.

Stereoscopic pair

Approximately 1 mile

FIGURE 108.—COASTAL PLAIN UNDERLAIN BY CLAY, SAND, AND GRAVEL (NEW JERSEY).

[Approximate scale 1 : 20,000. Photographs by Commodity Stabilization Service]

Cultivated areas are thin cappings of sand and gravel overlying clay formation. Lack of surface drainage rills in sand and gravel indicate that the capping material is well drained internally. Except for dark-toned crop vegetation the cultivated areas also have the general light tones commonly associated with well-drained materials. Note borrow pit in granular material at A. Streams flow in clay. The steep walls and flat bottoms of gul-

lies may not be typical of plastic clays in humid regions, however. Headward extent of small gullies generally ends abruptly against contact of clay with overlying sand and gravel. Vegetation growth is conspicuous along steep sides of gullies where trees have not been cleared for cultivation. Vegetation growth is locally favored by relatively constant supply of water that flows to surface along contact of clay with overlying sand and gravel.

Stereoscopic pair

Approximately 1 mile

FIGURE 109.—POLYGONALLY PATTERNED GROUND IN PERMAFROST AREA ALONG MAJOR STREAM
(NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

The susceptibility of low, poorly drained areas to the development of polygonally patterned ground resulting from ice-wedge formation is shown conspicuously along this major stream valley. Development of polygons, primarily low-center polygons, *A*, shown with relatively dark-toned centers and light-toned marginal ridges, has followed old channel scars representative of old slip-off slopes. Some high-center polygons, *B*, are also present. The angular gully pattern, *C*, is commonly found where ice wedges are melting

out of polygonally patterned ground. Also note serrated edges of oxbow lake, *D*, and rim of river terraces were ice wedges in polygonally patterned ground have melted out. Contrast appearance of poorly drained river terraces here with river terraces in nonpermafrost areas where internal drainage is generally good. The conspicuous tilt of the oxbow lake and up-hill flow of stream meanders indicate that tilt is present in the aerial photographs.

Stereoscopic pair

Approximately 1 mile

FIGURE 110.—WELL-DEVELOPED PINGO IN AREA OF PERMAFROST (NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

Partly drained lake basin, *A*, a particularly favorable area for development of permafrost, is conspicuous. Note old beach lines, *B*, shown by narrow bands of contrasting photographic tones and along which polygonal ground has developed. Low-center polygons having dark-toned centers and light-toned marginal ridges are abundant, as at *C*. High-center polygons

with light-toned centers and dark-toned marginal trenches, are also conspicuous in many places, as at *D*. Pingo, *E*, with a single crest crack here, is almost always diagnostic of underlying permafrost conditions. Also note pingolike forms, *F*, covered with polygonally patterned ground.

Stereoscopic pair

Approximately 1 mile

FIGURE 111.—AREA OF PERMAFROST (NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

Low, wet but drained lake basins, as at *A*, are favorable areas for the development of permafrost. Low-center polygons, *B*, shown as dark-toned depressed centers and light-toned raised edges are common. High-center polygons, *C*, exhibiting high, light-toned centers, and dark-toned marginal trenches, are also present. Pingolike forms, *D*, also covered with polygonally

patterned ground, are highly indicative of permanently frozen ground conditions. The serrated shoreline, *E*, of some lakes is typical of the thawing of polygonal ground and further suggests the presence of permafrost. Note floating ice, *F*; bottom of lake may be seen at edge of ice, and in places depth of water may be measured from the aerial photographs.

FIGURE 112.—CONSPICUOUS BEADED DRAINAGE IN AREA OF PERMAFROST (NORTHERN ALASKA).

[Approximate scale 1:20,000. Photographs by U.S. Navy]

Beaded drainage along main stream, shown as rounded pools of water connected by deeply incised watercourses, typically forms in areas underlain by permafrost. Note steep banks of pools, as at *A*, which have resulted from thawing of frozen ground and subsequent caving. Interpretation of permafrost conditions is supported by presence of high-center and low-center polygons. High-center polygons, *B*, generally are shown by relatively light-toned centers and dark-toned rims, although locally, as at *C*, the reverse tonal contrasts may be present. Low-center polygons with relatively dark-toned

depressed centers and light-toned raised rims are shown at *D*. The wetter areas, as in the partly abandoned drainage channel, *E*, or upper reaches of minor drainageways, are especially susceptible to formation of polygons. Area *F*, probably a small alluvial fan area, shows well-developed drainage. The angular pattern may indicate incipient polygon formation in contrast to the angular pattern of drainage, *G*, which is typical of areas where melting of ice wedges in polygonal ground is taking place.

Stereoscopic pair

Approximately 1 mile

FIGURE 113.—LANDSLIDE AREA IN VOLCANIC AND SEDIMENTARY TERRAIN (NEW MEXICO).

[Approximate scale 1:37,000. Photographs by U.S. Geological Survey]

Resistant flat-lying basaltic lava, *A*, caps mesa underlain by weakly resistant mudstone, shale, siltstone, and sandstone, a geologic environment particularly susceptible to the occurrence of landslides. Landslides, *B*, below lava cap are characterized by hummocky topography and local lobate

form suggestive of flowage. Note buildings, *C*, constructed on toe of slide areas. Recent lava flows are indicated by the dark photographic tone and irregular surfaces, *D*. The lobate character typical of flows can also be seen.

Stereoscopic pair

Approximately 1 mile

FIGURE 114.—DAMSITE AREA (SOUTHEASTERN ALASKA).

[Approximate scale 1:40,000. Photographs by U.S. Navy]

Conspicuous faults, indicated by linear topographic depressions *A*, *B*, *C*, and *D*, are present. The outlet of the lake itself appears to flow along a fault marked by the rectilinear depression *E*; this fault is probably the most

significant geologic structure in the area because a dam would have to straddle it. Highly fractured rocks comprise metamorphic types and intrusive quartz diorite.

FIGURE 115.—GRIDDED PHOTOGRAPH.

FIGURE 116.—GRIDDED BASE MAP OF AREA SHOWN IN FIGURE 115.

SOURCE AND IDENTIFYING DATA OF AERIAL PHOTOGRAPHS

The following table gives all data needed to identify the agency holding the negatives is not necessarily the the aerial photographs and also the agencies from which one that originally acquired the photographs. the aerial photographs may be purchased. Note that

INDEX

A	Page
Accuracy, in horizontal positioning.....	74-75
in vertical measurement.....	72-74
Altitude, determining differences of.....	53-54, 56
<i>See also</i> Flying height.	
Anaglyph principle.....	45, 47
Annular drainage. <i>See</i> Drainage, pattern.	
Anomaly, in drainage.....	26-27
in photographic tone.....	29
Anticline. <i>See</i> Folds.	
Association of features.....	11-12
Automatic dodging. <i>See</i> Photographs, printing of.	
B	
Base-height ratio.....	14
Beach erosion.....	39
Beaded drainage.....	38
Bedding.....	16, 19, 26
Botanical guides.....	32-33
C	
Cleavage.....	24
Climato, relation of soils to.....	15
Color, negative-type film.....	8
recognition element.....	8-9, 31, 36
transparencies.....	8, 31
Contours. <i>See</i> Structure contouring.	
Contrast. <i>See</i> Photographs, printing of.	
Control net or layout.....	67
D	
Dendritic drainage. <i>See</i> Drainage, pattern.	
Density, drainage.....	9
film.....	7
<i>See also</i> Drainage, texture.	
Diapositives.....	45-47
Difference in altitude, methods of determining.....	50-54, 56
Dipping beds, effect of vertical exaggeration.....	13-
estimation of dip.....	14, 64
measure of dip.....	64
54, 56-57, 63-64	
Dipping platen.....	63; fig. 32
Displacement, on faults.....	61
<i>See also</i> Radial displacement.	
Dodging. <i>See</i> Photographs, printing of.	
Double-projection instruments.....	45-48
Drainage, anomaly.....	26-27
beaded.....	38
pattern.....	11, 18, 19, 26, 27
texture.....	9, 16, 17, 26, 34-35
tributary-length relations.....	19
E	
Effective focal length.....	4
Elements of soil pattern.....	34-37
Engineering geology, interpretation of aerial photographs in.....	33-40
Engineering soil maps.....	33
Enlargement, of double-projection stereoscopic model.....	47-48
of paper prints.....	4, 54
ER-55 plotter.....	46, 47; fig. 17
Exaggerated-profile plotter.....	48; figs. 19, 20
Exaggeration. <i>See</i> Vertical exaggeration.	
Exaggeration factor.....	64
Extrusive rocks. <i>See</i> Igneous rocks.	

F	Page
Facies.....	30, 59-60
Faults, measuring displacement on.....	61
recognition.....	21, 29
Film and filters, effect on photographic image.....	4
panchromatic film-minus blue filter.....	4
Flat-lying beds.....	19
Floating dot.....	41, 47
Floating line.....	57-58, 64
Flying height.....	2, 4, 53-54
relation to radial displacement.....	75
relation to scale.....	2, 4, 53
relation to vertical exaggeration.....	14
Focal length, effective.....	4
relation to radial displacement.....	4
relation to scale and flying height.....	2, 4
relation to vertical exaggeration.....	14
Folds.....	19, 21, 26
Foliation. <i>See</i> Cleavage.	
Formulas, for determining differences in altitude.....	53, 56
for determining feet-equivalent of parallax measurements.....	54, 55, 72, 73
for determining radial displacement.....	75
for determining scale.....	2, 4
for determining stratigraphic thickness of inclined beds.....	figs. 26, 27, 28
Fractures. <i>See</i> Faults; Joints.	
G	
Gradient. <i>See</i> Stream gradient.	
Granular materials.....	33, 34, 35
Gridded base map.....	69; fig. 116
Gridded photograph.....	69; fig. 115
Ground conditions.....	33-39
Ground water.....	40
H	
Height, flying. <i>See</i> Flying height; also Difference in altitude.	
Horizontal position, accuracy of plotting.....	74-75
correction for.....	56-57
Hydrology, photogrammetric applications in.....	40-41
use of aerial photographs in.....	40-41
I	
Igneous rocks, extrusive.....	17
intrusive.....	17-18
Instrument capability.....	72-74
<i>See specific instruments.</i>	
Interpretation, defined.....	5
Interval measuring device.....	48; fig. 21
Intrusive rocks. <i>See</i> Igneous rocks.	
Isopach mapping.....	58-59
J	
Joints.....	16, 18, 19, 23-24
K	
KEK plotter.....	45
Kelsh plotter.....	47; fig. 18
K factor.....	54-55, 72-74; fig. 37
L	
Landform.....	6, 12-13, 17, 34
Landslides.....	39
Land use.....	37
Layout. <i>See</i> Control net.	
Lens angle, relation to parallax measurement.....	4
relation to radial displacement.....	4
Lineations.....	21, 29, 30-31
Lithologic guides.....	31

	Page
Lithology. <i>See</i> Igneous rocks; Metamorphic rocks; Sedimentary rocks.	
M	
Mahan plotter.....	45
Measurement, vertical. <i>See</i> Parallax.	
Metamorphic rocks.....	16, 18-19
Multiplex plotter.....	47; fig. 16
Multiscope.....	42, 45
O	
Ore deposits, interpretation of aerial photo- graphs in search for.....	30-33
Orientation of photographs.....	52; fig. 25
need for correct orientation.....	54
Orthophotographs.....	69
Overhead projectors.....	67, 68
Overlay, drainage.....	19
in correcting horizontal position.....	56
P	
Parallax, formulas.....	53
geologic uses of.....	56-63
measure of.....	50-55
Parallax bar. <i>See</i> Stereometer.	
Parallax ladder.....	41-42; fig. 12
Pattern, drainage.....	11, 26, 27
lines.....	9, 11, 29
soils.....	11, 29
vegetation.....	11
<i>See also</i> Elements of soil pattern.	
Permafrost.....	37-39
Permeability.....	16, 34-35
Petroleum geology, interpretation of aerial photographs in.....	24-30
Photogrammetric systems.....	69-72
Photographic tone.....	6-8, 16, 35-36
Photographs, geometry of.....	fig. 1
printing of.....	7
scale.....	2, 4
twin low-oblique.....	2, 4
Physiographic guides.....	31-32
Physiography. <i>See</i> Landform.	
Pingos.....	38
Platen.....	47
Plotting, in cross section.....	69
orthographic.....	67-68, 69
Plutonic rocks. <i>See</i> Igneous rocks.	
Polygonal microrelief.....	37-38
Pseudoscopic view.....	5; fig. 95
R	
Radial displacement, correction for.....	56, 68
measure of.....	56, 74-75
use in determining heights.....	56
Radial drainage. <i>See</i> Drainage, pattern.	
Radial planimetric plotter.....	42; fig. 14
Recognition elements.....	6-13
Reflectance. <i>See</i> Photographic tone; Spectral reflectance.	
Relief displacement. <i>See</i> Radial displace- ment.	
S	
Scale of photographs, relation to focal length and flying height.....	2, 4
relation to parallax measurements.....	4, 74
significance in interpretation.....	11-12, 14, 21
Sedimentary rocks.....	15, 16-17
Shadows.....	13

	Page
Shape.....	12-13, 34, 35
Size.....	13
Sketchmaster.....	42; fig. 13
Slope, direct determination of.....	63-64
measurement by parallax method.....	54, 56-57
Soils, permeability.....	34-35
transported, landform of.....	34
Spectral reflectance.....	7-8
Stereometer.....	41; fig. 10
Stereo slope comparator.....	63; fig. 33
Stereo slope meter.....	42; fig. 11
Stereotemplates.....	67
Stereotop.....	45; fig. 15
Stratigraphic thickness, determination of.....	57-58
Stream gradient, determination of.....	63
use in detecting tilt.....	55
Structure.....	19-24
Structure contouring.....	60-62
Structural guides.....	30-31

	Page
Surficial materials.....	17, 33
Syncline. <i>See</i> Folds.	
T	
Templets.....	67
Texture, drainage.....	9, 17, 26-27, 34-35
photographic.....	9
soil.....	9
topographic.....	9
Thaw lakes.....	38
Tilt.....	55
Tone. <i>See</i> Photographic tone.	
Topography, significance in delineating structure.....	19, 21, 24, 27, 29
<i>See also</i> Landform; Shape.	
Trellis drainage. <i>See</i> Drainage, pattern.	
Twin low-oblique photography. <i>See</i> Photographs.	
U	
Unconformity.....	24
Universal tracing table.....	48, 55; fig. 22

	Page
V	
Vegetation, as indicator of structure.....	11, 21, 23
in interpretation of permafrost.....	37
in interpretation of soils.....	36
significance in search for ground water.....	40
use in differentiating rock types.....	15, 17, 18
<i>See also</i> Elements of soil pattern.	
Vertical exaggeration, cause of.....	13-14
correction for.....	63, 64
relation to true distances and slopes.....	13-14
Vertical positioning.....	69
Viewing, methods of.....	4-5
Volcanic rocks. <i>See</i> Igneous rocks.	
V factor.....	73-74
W	
Water supply. <i>See</i> Ground water.	
Wave length.....	4, 7-8

Introduction

The following report presents standard methods used at the Center for Coastal Geology for the rectification of satellite imagery and the enhancement and normalization of dn (digital number) values in all bands to permit inter-scene comparisons. Minimal pre-processing is necessary when conducting a one-time analysis of satellite imagery for land cover within a particular area. However, when a time-series of imagery is compared or when an area encompassed by many images is analyzed, accurate and compatible spatial and spectral data must be employed.

The report is divided into two chapters. Chapter 1 is written as a generic approach to image processing with explanations of how and why particular steps are conducted. Chapter 2 presents image pre-processing, step-by-step, as would be conducted with PCI, Inc. software on Landsat satellite imagery. The imagery utilized is entirely Landsat TM (Thematic Mapper) and MSS (Multi-spectral Scanner).

The first chapter includes basic image pre-processing steps in a generic format with equations for indices and calibrations. The theory and general approach may be applied to other imagery types and software. Although there will be specific references to the particulars of our own project and resources, these techniques may be creatively adapted to suit other research needs. Appendix A provides an outline of the pre-processing steps.

The second chapter covers image processing with PCI, Inc., as conducted on the Florida Big Bend coastal wetlands project. The chapter addresses software-specific parameters for each procedure, details on implementation, and includes a flow chart for PCI EASI procedures. The procedures included will

permit the subsequent pre-processing of imagery in a manner suitable for additional time-series analysis.

Satellite imagery used in the detection of change along coastlines is processed in a standardized fashion to ensure temporal, spatial, and spectral compatibility between scenes. Imagery is initially selected to correlate as closely as possible with season and time-of-year coincident with high biomass and favorable atmospheric conditions as appropriate per region. Tide level at time of overpass in coastal areas can be critical in the evaluation of between-scene differences in the intertidal zone. However, due to cloud cover and image availability, tide level variations are accepted as an inherent limitation to inter-scene compatibility.

Imagery is registered to the UTM coordinate system using GPS-collected (Global Positioning System) ground control points, achieving inter-scene compatibility of < one pixel for Landsat TM. All images meet map accuracy standards of 1:25,000. Radiometric calibration and solar atmospheric correction are performed on all images to derive surface reflectance dn values in each band. The calculation of surface reflectance permits change analysis to be based on relative spectral changes or changes in vegetation biomass with less emphasis placed on land cover category variations. A vegetation index and wetness index is calculated for each image. The resulting pre-processed imagery is ready for inter-scene comparisons.

The procedures used here represent an implementation of techniques by Dobson et al. (1995), a document which describes approaches recommended by the NOAA Coastal Change Analysis Program (C-CAP).

Chapter 1

Image processing methods

1.1 SCENE SELECTION

1.1.1 Season

Initial imagery selection includes determination of the appropriate dates and time frame for analysis. Leaf-off, or winter aerial photography, has traditionally been used in the determination of wetland habitats. However, satellite imagery does not have the same spectral and textural clues as aerial photography and must be employed in a different manner to identify land cover and change detection. Spring imagery is selected for the Gulf coast sub-tropical environment to maximize distinctions in vegetative health and quantity by providing maximum biomass during a period with a high probability of haze-free images. Biomass would not be adequately identified in winter imagery. The selection of imagery dates must be region and project-specific and should be advised by local ecologists familiar with the territory and the particular research issue.

Our primary project area is in the Big Bend region of the Florida Gulf coast (Figure 1). Two scenes are required to cover the area, and two seasons are required to fully classify the land cover. Winter imagery is used to augment the spring imagery for the distinction and classification of deciduous vegetation. A total of four coordinated scenes were acquired for the base years in the analysis (Table 1). Supplementary analysis in the time series requires contemporary spring scenes for each additional year.

1.1.2 Water Level

Tide levels can adversely affect the determination of intertidal environments. It is preferable to select scenes with similar low water levels to optimize the characterization of low elevation intertidal zones. Each additional decimeter of water contributes to the mis-identification of 1-1.5% of the intertidal zone as

documented by Jensen et al. (1993), and Raabe and Stumpf (1997). C-CAP recommends selecting tide levels within 0.3 - 0.6 m of mean low water (MLW), which maximizes the utility of the imagery (Dobson et al., 1995). The tide range in the study area is approximately 1 m from MLLW (Mean Lower Low Water) to MHHW (Mean Higher High Water). Although the majority of the intertidal environment along the Big Bend is high marsh, low water level at the time of satellite overpass enhances the discrimination of the low intertidal environment.

Due to a combination of factors such as cloud cover and scene availability, the imagery secured for the Big Bend does not entirely fit the C-CAP standards, but is the best available for the analysis. Some variability in water level is acceptable if two scenes per year are employed in the analysis. In the Big Bend we found that a complementary scene near MLW in the same year can facilitate the correction of differences caused by water level (Table 1). The 1986 south imagery exhibits high water level in both winter and spring, and consequently poses the greatest difficulty in identifying low elevation intertidal habitats.

Table 1. Landsat TM images and Cedar Key water level at time of overpass

Landsat coordinates path/row	Location	Date	Cedar Key water level (msl)
18/39	Tallahassee, FL	01/23/85	0.40
18/39	Tallahassee, FL	04/25/86	1.05
18/39	Tallahassee, FL	11/29/93	0.71
18/39	Tallahassee, FL	04/09/95	1.46
17/40	Cedar Key, FL	01/16/85	1.18
17/40	Cedar Key, FL	04/25/86	1.29
17/40	Cedar Key, FL	01/12/95	1.26
17/40	Cedar Key, FL	04/02/95	0.54

1.1.3 Cloud cover

Cloud cover is the most limiting parameter in scene selection. Listings may be misleading, and previews of imagery should be made whenever possible to ensure quality data before purchase. Although it is advisable to select entirely cloud-free imagery, in some cases it may be necessary to establish only that the critical study area is cloud-free.

1.1.4 Simultaneous coverage

When a study area is large and/or encompasses more than one scene, simultaneous coverage of the whole area is warranted. It is possible, under ideal conditions, to secure several images within days or at most within 3-4 weeks that cover the entire area. In the instance where a study area falls between two scenes in the same path, it is possible to order an image that straddles the image boundaries, eliminating the need to mosaic scenes together.

1.1.5 Specifications

The CD-ROM Format

Imagery obtained from the EROS Data Center (EDC) and EOSAT is now provided in CD-ROM format. The procedures that follow begin with this format. Other formats may be accommodated with minor adjustments in the initial steps. All imagery for this project is obtained in Space Oblique Mercator (SOM) and with Nearest Neighbor resampling (NN). NN resampling is recommended for studies involving spectral analyses because it minimizes alterations to the count values. Other resampling such as cubic convolution may be preferred in studies involving pattern recognition.

1.2 SCENE PREPARATION

1.2.1 Download raw imagery

The contents of the CDROM will include 7 bands of TM along with summary and header files. All 7 bands of data are extracted from the CD and converted to a readable format for image processing. The header file is also extracted at this point.

The PCI procedures, CDEOSAT and CDNLAPS, read data off the CD-ROM, create a new file on disk, write the band data, and extract header information which is written into an orbital segment attached to the new file. The orbital segment will be used in the rectification of the imagery to the UTM coordinate system. Other coordinate systems may be employed in a similar manner.

1.2.2 Check header file

The header file should accompany the scene and a readable copy of the header file is made to disk. A sample header file may be found in Appendix B. Information from the header file is used in subsequent processing steps. Trailer files may or may not accompany the imagery. Typically, the information desired from this file is the time of overpass in Greenwich Mean Time (GMT), which is noted for use in the radiometric enhancement.

1.2.3 Visual check

All new imagery is previewed, band-by-band, to determine if data lines are missing or other anomalous features exist in the scene. The visual review must be done at full-resolution. Attention is focused on identifying lines or blocks of missing data in each band for subsequent "repair." Haze or cloud cover that may render parts of the scene ineffective for analysis is noted as well. In our case the visual check is conducted in PCI Imageworks with seven image planes in the display window. Each portion of the image is displayed at full-resolution, and each band is viewed separately to identify missing data.

It is useful to examine the range and histogram of count values in each band at this time. Occasionally imagery is purchased with offset or anomalous count values. A quick evaluation now may save time later. Band 6, the thermal band, is especially prone to such errors.

1.2.4 Line replacement and destriping

Missing lines are "repaired," and other problems are resolved in each band before the scene is rectified to the UTM coordinate system. Once rectification has been conducted, errors

will no longer coincide with horizontal lines of data and are virtually impossible to fix. Image line replacement is a simple procedure that allows the operator to fill-in missing lines with the line above, below, or with an average of the two.

It also may be necessary to conduct destriping of the image if a linear pattern is prominent in the image. It is usually a more significant problem with Landsat MSS than with TM or SPOT, and affects dark objects such as water in particular. However, we have run several variations of a destriping procedure on scenes with an 8 to 9-line repetitive stripe and have concluded that the output image was not improved over the original. Although we do not conduct this procedure ourselves, it may be advisable in other situations, and, if necessary, must be attempted in this initial phase of pre-processing, before rectification.

1.3 ORTHORECTIFICATION OF IMAGERY

Rectification of the imagery requires several steps: identification of ground control within the imagery, collection of ground control points with a GPS unit, development of a rectification model, reprojection of the imagery using the model, and two accuracy checks.

Three terms are defined:

1. Rectification fixes each feature in the imagery to the correct position on the earth
2. Reprojection involves transforming and rectifying the image to a standard projection such as Universal Transverse Mercator (UTM)
3. Registration involves having features in multiple scenes exactly match each other in location

Ideally, the rectification and reprojection will inherently produce co-registered images. We use rectification and reprojection procedures which result in sufficient accuracy to produce co-registered scenes. The reprojection is critical in that it produces images in a standard projection such as UTM or state plane.

However, in some projects, a previously rectified scene might be used as reference so that

all scenes are registered to the base scene. For instance, a set of Landsat MSS scenes might be registered to a NALC (North American Land Characterization) scene. If the above or other procedures are used where a polynomial transform "rubber sheet" adjustment is employed, it is usually preferable to co-register scenes, then conduct the reprojection and rectification on all of them. Co-registration without rectification is never recommended.

1.3.1 Coordinate System

Rectification and reprojection of satellite imagery to a standard coordinate system is performed on all scenes in the project. Whether you use UTM or another coordinate system, the reprojection allows the determination of geographic coordinates for features identified in the analysis and facilitates integration with other geographic data sets. The approach used in the Big Bend project employs a PCI procedure, SORTHO, which reprojects the image based on satellite orbital information and a set of standard ground control points. The results effectively combine both inter-scene compatibility and coordinate plane rectification. To achieve co-registration without rubber sheeting, a common set of ground control points is used for all images. In this way the original data is rectified and reprojected from the Space Oblique Mercator (SOM) projection of the raw data to the Universal Transverse Mercator (UTM) coordinate system, with corresponding results in each subsequent image rectification.

1.3.2 Ground control in image

Ground control points are identified in the imagery as clearly visible point or right-angle positions, which are also accessible by road. Approximately twice as many points are identified as are ultimately required for the registration for several reasons. Some positions are not retrievable in the field, not all positions are identifiable in all imagery, and some positions are held out as part of the registration accuracy check. The operator examines a full-resolution image display to select the ground control. Preferred locations are corners at small to intermediate right-angle road intersections in rural or low-density developed areas. Highly developed areas tend to give blurred intersections and are difficult to re-locate in subsequent

imagery. The identification of visible and distinct locations in the imagery which are also accessible to a field team is a major challenge in many regions. Alternatives to road intersections and right angles may be selected based on other landscape features. For example, the end of a bridge over a stream may be suitable. Consideration is given to the clarity of the location and the possibility of re-identification of the same point in earlier and later imagery. Good judgment and careful selection ensures accurate registration of the study area.

The set of selected positions are marked on the imagery file with a vector which can be displayed on a field laptop computer for identification during the field reconnaissance. If the technology is not available, a hardcopy is printed of each potential ground control point in the imagery, and these are bound with map sheets to aid in field identification.

1.3.3 Ground control in field

Accurate ground control points are collected for each image based on pre-identified locations as described in section 3.2. A hand-held Global Positioning System (GPS) unit is employed with accuracy guaranteed 5-10 m. Positioning of < 10 m requires differential, P-code, or comparable receivers for accurate rectification of Landsat TM or SPOT imagery. Standard non-differential units do not produce the necessary sub-pixel accuracy.

Field plans should include 5-10 minutes per station for data collection and site documentation to facilitate identification of the positions in subsequent imagery. We recommend a minimum of 2-3 readings per position, and 24-30 positions per image. The ground control should be well-distributed across the image and at locations which are visible in imagery over a period of 5-10 years. As some GPS readings turn out to be poor quality, we recommend collecting multiple readings at each location. Accurate and complete field notes accompanying the collection of GPS ground control facilitate the identification of the positions in subsequent imagery. A description including county, road, and intersection names, distance from nearby intersections, directional designators, and photographs are helpful in future relocation. We have also concluded that the occupation of an intersection corner,

appropriately designated (as in "southwest corner"), is better than occupying the center of a road intersection as has been previously practiced.

Other techniques exist for the collection of ground control points and may be applied where resources are limited. For instance, low-cost, non-differential, non-P-code GPS receivers can be used, providing positional accuracy of 30-100 m. Map accuracy will be reduced from the 1:25,000 achieved in this project to 1:50,000 or more. Alternative approaches include digitization of positions from mylar 7.5 minute quadrangles, or the selection of similar positions from digital data sets including vectors, digital orthophotographs, and other imagery. Each approach carries with it inherent errors, of which the analyst should be aware. At the very least, the operator should know the error range for the input coordinates prior to the analysis. This will determine an acceptable RMS error range and whether or not the intended and final map accuracy will be achieved. The same caution applies to the selection of alternative adjustment techniques.

The PCI software in use for this project has a field version of GCPWORKS (under our investigation), which incorporates the selection of ground control in the imagery and the collection of GPS ground control simultaneously, on a field laptop computer. Although this does not eliminate the need to carefully select quality and well-distributed control within the image and in the field, it does consolidate the work, and allows the operator to evaluate the quality of the ground control *as it is being collected*. The on-site development of a rectification model eliminates costly returns to the field in the event some ground control proves useless.

The GPS unit employed in this project has a stated accuracy of ≤ 10 m, which met our mapping needs with TM and MSS. Higher resolution imagery such as SPOT and IRS may benefit from even higher accuracy ground control, available with newer GPS units at 1-5 m. Although 24-30 positions are collected per image, not every position is used in the actual rectification. In addition to the elimination of poor quality positions, other ground control points are not easily relocated in the imagery and are not used. Eight to ten positions are used to rectify the imagery, and another 10-12 are set aside to be used in the accuracy check.

1.3.4 Create model

A model is created with the ground control points. It is preferable to use a low-order polynomial transform to reduce distortion in the final image, particularly at scene edges or over large water bodies. The PCI procedure we use makes the conversion between the two systems without introducing distortion to the resulting image as is normally found in polynomial adjustments. We prefer this approach as it gives consistent spatial positioning across the image. Other registration packages are available and may be applied with varying results depending on the quality of the ground control and the amount of distortion introduced in the polynomial function.

User-entered coordinates

Imagery is brought to display on the monitor for the collection and identification of ground control points. These ground control points are part of the original set selected from the imagery at full-resolution display and subsequently collected in the field. They are spatially well-distributed over the extent of the image and show promise of being stable and easily identifiable in a time series. The GPS coordinates collected at these locations show little variation in repeat readings.

During the identification of ground control, watch the RMS (root mean square) error for each ground control point and the total RMS error in both x and y. Examine the scatter plot of the ground control to help identify positions which are in error. Within reason, it is possible to adjust the location of the ground control in the imagery to achieve optimal positioning and distortion-free rectification.

We have found with 10 m accuracy in the GPS and 30 m resolution in the imagery that the RMS of each individual position and the total RMS need not exceed 0.5 pixels (15 m). At the same time, consider that excessive adjustment of point positions to produce significantly lower RMS readings will introduce errors in the final adjustment. An RMS of 0.5 pixels indicates that the position is ± 15 m or 1/2 pixel from the optimal location. Under the circumstances, it is reasonable to expect a total RMS of 0.3-0.6 pixels, or 10 - 20 m, best fits the accuracy achievable with the given data. We have found that substantially forcing the model to lower

errors introduces regional distortion into the final image.

Model

The collection of ground control points in the imagery leads to the development of a model to adjust the full image to the new coordinate system. See Chapter 2 for detailed steps in PCI. If not running GCPWORKS, and SMODEL, follow appropriate steps for software application.

1.3.5 Satellite image rectification

The goal of image rectification is to facilitate the overlay of additional imagery and other geographic data sets. A standard map area, with boundaries set in UTM, is established for each scene, thus all image files for the same region, once rectified, will occupy the same map area. The UTM bounds for the scene are established according to the file size, the 28.5 x 28.5 m pixels (57 x 57 m pixels for Landsat MSS), and the minimum/maximum northing and easting required to contain the full scene area. These boundaries, the UTM zone and the ellipsoid are established on each newly-created empty file.

The size and initial boundaries for the two scenes in the study (Figures 2 and 3) are shown in Table 2 with UTM zone 17 coordinates for the upper left and lower right corners. The north image is cut at the Florida/Georgia border, approximately - 1100 lines (Figure 3). A new file of matching size is created for each image in the series. A matching georeference segment is established on each file. Details are provided in Chapter 2.

Figure 2. Rectification and reprojection from SOM to UTM, Landsat Path 17 Row 40.

Figure 3. Rectification and reprojection from SOM to UTM, Landsat Path 18 Row 39

In the event new regions are processed under these instructions, the designation of an output file size and geographic extent will depend on project needs, although it is recommended that full, or close to full scenes are pre-processed to maximize their subsequent utility. The calculation of file size is determined by the maximum and minimum eastings and

northings of the raw image and the pixel size. Pixels in Landsat TM are 28.5 x 28.5 m, in MSS the pixel size is 57 x 57 m. Image rectification is conducted with the model segment created earlier, and the output applied to the newly-created and georeferenced image file discussed in the preceding paragraph.

Table 2. Scene size and coordinates for georeferencing segment

Landsat TM Big Bend File Information	Scene Location	
	Tallahassee	Cedar Key
Path/Row	18/39	17/40
Initial file size	6967 pixels/5965 lines	6967 pixels/5965 lines
Final file size (x/y)	7556 pixels/5412 lines	7916 pixels/7112 lines
Pixel size (x/y in meters)	28.5/28.5	28.5/28.5
Upper left coordinates (UTM)	98560 E, 3408400 N	210287 E, 3296110 N
Lower right coordinates (UTM)	313906 E, 3254158 N	435893 E, 3093418 N

1.3.6 Accuracy check

Accuracy checks involve both geographic or map accuracy, and co-registration or inter-scene accuracy. It is important to recognize that multiple scenes may meet one criteria and not the other. Two scenes may be co-registered to within a pixel, but have significant geographic error. Conversely, scenes may meet a standard map accuracy in a selected coordinate system, but have systematic errors that result in poor co-registration between scenes. Mis-registration may result from poor models or the use of high order polynomials. Evaluation of both map accuracy and image co-registration is necessary subsequent to image reprojection.

UTM or coordinate system accuracy

Image rectification is not complete without accuracy checks. If check points were not entered and evaluated as in GCPWORKS and SMODEL above, it is necessary at this point to objectively locate 8-12 check points in the rectified image. The evaluation will give a measure of the map accuracy, the percentage of the image within the standard 'x' m. Obviously the evaluation varies according to the resolution of the imagery, the accuracy of the ground

control, and the intended accuracy for the particular study. The measure obtained tells the user the expected positional accuracy of the majority of features in the image.

The check points are part of the larger set of ground control established with GPS as described in 1.3.2 and 1.3.3. Visually locate each ground control check point with the cursor in the rectified image. Note the image coordinates at the location, and evaluate how far the position is from the known x,y (UTM) coordinates. It may be difficult to conduct this step objectively. Try evaluating the *portion* of a pixel from which your visual position strays from the coordinates at which it visually should be. In our case, the goal was to accurately map 90% or more of the map features within 20 m of their known location, so we evaluate each position relative to our objective.

The accuracy check of the image to the UTM coordinate system meets our needs and is acceptable. Clearly, with only 12 check points, only one position per x/y component can exceed the established tolerance. It is worth conducting a careful check at this point to ensure good geographic correlation of data. If there is a geographic error in the image, it helps if you

have indicated in which direction it shifted with a simple $\pm$ after each x/y offset.

Inter-image accuracy

The second accuracy check is conducted on imagery which will be used in inter-scene comparisons. It has been a common practice to rectify only one image, and then register all other images to the base scene, or to co-register all scenes to a master and apply the rectification for that scene to all others. While the standard approach provides a solution to multiple-image registration, every image in the present study is rectified individually to UTM coordinate system. According to this approach, each subsequent image is rectified using the same set of ground control points, and is visually checked against the original, or first-rectified base image as follows.

The inter-scene accuracy check consists of selecting 3 to 4 areas within the image to be displayed, one by one, at full resolution with selected bands from each image. Two methods are used to check inter-scene registration: (1) a simultaneous display of the same band from both scenes, using color as a reference to examine horizontal and vertical linear features, (2) a flicker state between the two scenes with the cursor at a fixed, well-defined location. Both methods may be applied regardless of the software in use.

In the first method single bands, usually band 4 or 3, from each scene are displayed simultaneously in a red-green-blue (RGB) display. Offsets will be obvious in either the x or y direction as bands of color on either side of a vertical or horizontal roadway (Plate 1). The first evaluation gives a quick check on overall alignment of the two images.

In the second approach the bands from the base image are displayed simultaneously with the same bands from the new image in a multiple-image plane display and set to flicker state. Three to five right-angle road intersections which display true horizontal and vertical direction within the image are evaluated in each of the selected full-resolution windows. Each intersection is evaluated and recorded in a table (see Chapter 2.2.7).

Plate 2 illustrates the position of the cursor at a right angle road intersection in the base image and evaluation of the cursor position

relative to the intersection in the newly-rectified image. The cursor is placed at the center of the intersection in the base image, as if two imaginary lines were drawn N/S and E/W, taking into consideration the mixed pixel effect. The display is flickered to the newly-registered image, and the location of the intersection is compared in half pixel increments. Roads and intersections at non-right angles to the pixel/line orientation are never used in this evaluation. See Plate 3 for examples of intersections preferred for evaluation. The second method provides the operator with a detailed evaluation of inter-scene compatibility and the direction of offsets, if any.

Expected inter-scene registration is $\pm$ one pixel. A trend of greater than one pixel in x or y requires re-examination of the ground control point segment and a repeat of the whole rectification process. Consistent offsets or regional trends of greater than one pixel suggest poor quality registration and require re-rectification of the imagery with a thorough evaluation of the ground control point coordinates, positioning, and land cover changes between the imagery dates.

Again, good judgment, and a second opinion may help to eliminate operator errors or unforeseen problems. All imagery in the current project must meet the $\pm$ one pixel inter-scene accuracy before additional processing can be conducted. The goal is consistently met and presents no real problem with this particular set of imagery. We encourage other projects to develop similar methods to achieve high inter-scene positional registration.

1.4 RADIOMETRIC AND ATMOSPHERIC CORRECTIONS

Several band enhancements and corrections are applied to the rectified imagery to normalize the dn (digital number) values, facilitating direct spectral comparisons between imagery bands and a comparable set of values as input to indices and clustering programs. Radiometric calibration, conversion to reflectance or solar correction, and atmospheric correction are conducted on every image. The adjustments rely heavily on data contained within the header file, including gain, bias, and solar zenith angle. Programs have been written in-

house to facilitate the radiometric and atmospheric corrections. The aerosol adjustment still relies on a visual/manual assessment of dark water values, although it may also be automated eventually.

1.4.1 Radiometric correction

The digital counts in the image are transformed to reflectance using the calibration that comes with the files and the equations and constants of Price (1987), and Markham and Barker (1985):

EQUATION 1. REFLECTANCE CALIBRATION

$$R(\lambda) = \frac{\pi L(\lambda)}{E_0(\lambda)(1/r^2) \cos(\theta_0)} \quad 1$$

where λ is the band; the radiance, L , is determined by:

EQUATION 2. RADIANCE

$$L = G * N + BIAS \quad 2$$

E_0 is the solar constant (Price, 1987; Markham and Barker, 1985), r is the normalized earth-sun distance, θ_0 is the solar zenith angle at the image center, N is the digital count, G is the calibration slope, and $BIAS$ is the calibration offset for zero radiance. A scale factor of 500 is applied to bands 1,2,3,4,5, and 7 to convert to 1 byte per pixel (0-255). A scale factor of 100 is applied to band 6. More sophisticated computations for reflectance exist. These involve additional terms in equation 1 for atmospheric transmission, and are being considered for implementation.

1.4.2 Atmospheric correction

The atmosphere introduces two forms of path radiance into the signal, radiance from Rayleigh or molecular scatter, and radiance from aerosols or haze. These can be removed simultaneously using dark object subtractions. However, improvements in atmospheric correction offers advantages in treating atmospheric and Rayleigh corrections separately. If no dark water exists in the scene, the Rayleigh correction is critical.

Rayleigh radiance is removed before the dark object subtraction. While not critical, when dark water is present, removal of the Rayleigh path radiance permits pixel by pixel correction of aerosols for water pixels and allows better control on the adjustment for aerosols. The Rayleigh term is determined using standard equations and coefficients. Models such as LOWTRAN (Air Force) can be used for the solution.

1.4.3 Aerosol correction

The aerosol correction is performed using subtraction from bands 1-4. Because the Big Bend region has black-water lakes and rivers, water can be found that has negligible reflectance in all bands. A dark-object subtraction is used, with the reflectance of the darkest water being the value subtracted. The correction is either constant or decreases slightly with wavelength (Chavez, 1989). The dn value selected should be that corresponding to the lowest value that has a significant number of pixels. In bands 3 and 4 the dark water area should be the same region. Identifying dark water in the blue and green bands may be difficult. If a suitable area is not present, extrapolation from bands 3 and 4 may be necessary.

9	10	9	13	10
8	5	8	7	8

The foregoing values represent pixels in the darkest water area of a scene. The 5 and 13 values are probably artifacts of the sensor (or boats). A value of 8 would be appropriate for dark water subtraction.

Normalization of marsh for bands 3 and 4 is determined in the image overlap. By convention, we use values of zero to define missing data. A simple model is applied to all bands to restore zeroes to a value of one within the image bitmap. The non-image area surrounding the scene is eliminated from this and the index calculations by the application of an "image-only" mask, detailed in Chapter 2.3 and 2.4.1.

1.5 INDICES

Analysis includes the calculation of a vegetation index, wetness index, temperature, and water reflectance. Each index provides a means to compare a particular feature between different scenes.

1.5.1 Vegetation Index

Subsequent analysis uses band ratioing as a surrogate measure of biomass. The vegetation index is a ratio of TM bands 3 and 4. The normalized difference vegetation index (NDVI) is a quantification of green biomass. It is not meaningful for water.

EQUATION 3. NDVI (NORMALIZED DIFFERENCE VEGETATION INDEX)

$$NDVI = \frac{R(4) - R(3)}{R(4) + R(3)} \quad 3$$

where 4 and 3 are near-infrared and red bands, respectively, and R = reflectance after aerosol correction. A weight of 0.01 for the ratio denominator will scale NDVI by 100, such that an NDVI of 1.0 produces a count of 100.

1.5.2 Wetness Index

The wetness index is a measure of the wetness in the soil observable through the canopy and is particularly effective in distinguishing tidal influence in the coastal marsh zone and in areas with thin vegetation canopy. It is calculated based on the inversion of a procedure used to delineate open or standing water. We find that the gradient provided with the inverse, the "wetness index", shown here is effective in delineating the extent of tidal flooding in the coastal marshes.

EQUATION 4. WETNESS INDEX

$$WETNESS = R(5) - R(2)$$

1.5.3 Temperature

Temperature is calculated from the thermal band, TM band 6. The contrast in water temperatures is particularly noteworthy in Florida gulf coastal waters during the winter season,

when it is possible to observe the source and redistribution patterns of the relatively warmer waters of the Floridan aquifer. We convert radiance of TM band 6 to Celsius + 5. Resulting values include freezing temperatures, which may occasionally occur in the region.

EQUATION 5. TEMPERATURE IN CELSIUS

$$\text{Celsius} + 5 =$$

$$(1260.56 / \ln(60.776 / (L(6)/100) + 1)) - 268)$$

1.5.4 Water Reflectance

Water reflectance is calculated as the difference of bands 2 and 4.

EQUATION 6. WATER REFLECTANCE

$$\text{Water reflectance} = R(2) - R(4)$$

Chapter 2

Image processing software procedures

2.0 INTRODUCTION

Many of the image pre-processing steps are conducted within an image-processing software package. The Center for Coastal Geology group uses PCI, Inc. The following chapter includes specific instructions on running the procedures. It should serve as a guide to the basic steps required within this program.

Initial scene selection and ordering is conducted outside of the image processing package. A flow chart (Plate 4) is provided to help the novice follow the different kinds of steps involved and the order in which they are conducted. The check list in Appendix A should become the basis for your own notes, including adjustments and new developments.

2.1 SCENE PREPARATION

Imagery is downloaded from the CD-ROM disk with CDNLAPS or CDEOSAT, depending on the format of the disk. Important information is included in the header file. Take time to learn to read the header file with the instructions accompanying your order. Look for format (NLAPS or EOSAT), band sequential or pixel interleaved (BSQ, BIL), number of pixels and lines, date and time of acquisition, resampling scheme (NN, CC, BL), and so on.

Once downloaded to a .pix file, examine each band at full resolution for missing lines or blocks of missing data, heavy clouds, and the histogram of dn values. Each band should exhibit a normal range and distribution for the season and region covered. Now is the time to repair or return an image with serious problems.

Table 3 shows the parameters set for CDNLAPS. Table 4 shows parameters set for LRP to fix line number 100 in band 2 with the mean from the line above and the line below. The EASI procedure, LRP, requires the operator to specify the missing line(s) +1 to correctly identify the lines to be replaced. If destriping is attempted, read about DSTRIPE in EASI help.

2.2 ORTHORECTIFICATION OF IMAGERY

The orbital segment created in CDEOSAT or CDNLAPS contains information used in an adjustment between the estimated latitude/longitude of the raw imagery and the desired coordinate system. SMODEL creates a model from the orbital segment and a ground control point segment. The ground control point segment is created in GCPWORKS.

2.2.1 GCPWORKS

Imagery for the Florida Wetlands is rectified with ground control collected with GPS units and is reprojected to the UTM coordinate system. Ground control selection is described in Chapter 1, and can be conducted in any image display program, including PCI's IMAGEWORKS. Once the ground control has been identified and field collected, run GCPWORKS to enter the coordinates at their respective locations in the image. The satellite orthorectification option is selected to permit the use of the orbital segment in the model.

Select "Collect/review GCP's only", "Satellite Ortho Correction", "User Entered Coordinates", and then "Select Uncorrected Image". Enter the path and filename of the nlaps.pix file. Load three bands, usually natural color (3,2,1) or false color (4,3,2), are preferred for display. Set the units to meter, and the coordinate system to UTM, zone 17, row R and ellipsoid WGS84. Obviously, the zone and row will change depending on the region. Identify the location of 8 to 12 ground control points and enter the corresponding UTM coordinates collected with the GPS unit.

During the identification of ground control within GCPWORKS, watch the RMS error for each ground control point and the total RMS in both x and y. Within reason, it is possible to adjust the location of the ground control in the imagery to achieve optimal positioning and distortion-free rectification.

In GCPWORKS it is possible to also enter accuracy check points at this time. If not working in this program, these check points are set aside for a post-rectification accuracy check. The 10-12 accuracy check points must be of

equally high quality and well-distributed about the scene. Care is given to treat these positions and the associated error objectively, as they eventually provide a measure of the model's accuracy. These positions should be entered at the end, when the ground control points have been securely identified to avoid adjusting the model to fit the check points. When the operator is satisfied with the location of the ground control and the total RMS error, the ground control point segment is saved within GCPWORKS. Ideally, this will be segment #3.

2.2.2 GCPREP

A report documenting the ground control point segment as collected is obtained by running GCPREP. Run the procedure with ORDER set to 0. GCPREP produces a text file showing the list of ground control points, their pixel/line locations, the user-entered coordinates, and errors. The UTM coordinates of the ground control is exactly what was entered within GCPWORKS. This will change when the model is run in SMODEL. Remember, in GCPWORKS, the satellite orthorectification was selected. This forces the orbital segment to be referenced while developing the model. GCPREP does *not* refer to the orbital segment, and thus does not reflect it's influence on the ground control. The output from another procedure, GCPWRIT, may be useful in creating a vector segment. It requires a little editing and then running VREAD. The vector may be displayed in subsequent displays to help re-locate the ground control points for new imagery.

2.2.3. SMODEL

SMODEL draws on both the orbital segment and the ground control point segment to create the model, and must always be run on the whole scene. It is ineffective to run on a partial scene. If check points were entered along with the ground control, SMODEL will also produce a table showing the accuracy of the check points in meters. Run SMODEL as shown in Table 5. Both the orbital segment, 2, and the ground control point segment, 3, must be specified in the procedure. SMODEL produces a model segment, normally 4, which will be applied in the image rectification, SORTHO.

SMODEL also produces a report showing the accuracy of the check points in meters. Examine the report for values outside of the range of expected and desired accuracy (see Appendix C). Excessive values below the original 10 m accuracy of the GPS positions may introduce distortion to the final image rectification. Values greater than 20 m, or 2/3 pixel, suggest the overall registration may not meet inter-scene registration requirements. Note also that the UTM coordinates shift by the RMS error.

Values for positional accuracy in this project are acceptable between 8-20 m. The rectification of a TM scene will technically meet 1:25,000 map accuracy standards, provided that 90% or more of the individual accuracy check points are within 20 m or less of their desired location. With 12 check points, only one can be ≥ 20 m from its true location. Although we achieve the reported level of map accuracy, TM imagery will always be printed at scales of 1:50,000 or smaller to avoid the blocky appearance of the pixels.

2.2.4 CIM2 - New file creation

New imagery files are created in CIM2, a file format which creates a separate file for each band, all associated by the header or .pix file (Table 6). The size of a fully-processed full size Landsat TM scene makes this option appealing for ease of movement and disk-space issues. The example shows the standard size of

the north Big Bend image, path 18, row 39. The size includes the removal of ~1100 lines in the state of Georgia and the enlargement of the file to reproject the region into the UTM coordinate system (see Figure 3). All north scenes will be created in the same manner. If working in another region, establish a standard file size based on the full extent of the UTM eastings and northings and the pixel size.

2.2.5 GEOSSET - georeference segment

Every file in PCI has a georeferencing segment created automatically as segment 1.

The geographic boundaries, the UTM zone, and the ellipsoid are set in the georeferencing segment of the newly created CIM2 file with GEOSSET. An example for the north Big Bend is shown in Table 7. The coordinates given are applied to each corresponding image, making overlays and inter-scene analysis a simple task.

2.2.6 SORTHO - satellite image orthorectification

Orthorectification of imagery is conducted in PCI with the SORTHO procedure which applies the model segment to the nlaps image file and reprojects the seven bands of data into the empty bands of the newly created and georeferenced .pix file. See Table 8 for SORTHO parameters.

Due to the minimal topographic variation along the Big Bend coast of Florida, we do not employ a DEM file. Instead, we estimate an average value for elevation as the width of one pixel with no offset (ESCALE). Elevations do not exceed ~60 m in the area, and this appears to be sufficient for positional accuracy and inter-scene registration. The need for elevation must be determined on a region-by-region basis. . The SORTHO procedure may take up to 6 hours on a SUN SPARC 20 and is usually run overnight.

2.2.7 Inter-scene accuracy check

The inter-scene registration accuracy check is conducted manually within an image display program. Run IMAGEWORKS with a full-resolution window ~600 x 800 with 6 image planes. Display 3-5 well-distributed regions in the window, each time loading the newly

registered image (4,3,2) and the base image (4,3,2) with the same input window.

For instance, in image planes 1,2,3 load the new image (4,3,2) with an input window of 300, 300 (x,y offsets), 600, 800 (x,y window size). Then load the base image to image planes 4,5,6 (4,3,2) using the same full-resolution window. Examine the images first with a single

band from each of the images in a RGB display mode. An example may be viewed in Plate 3. Look for truly horizontal or vertical roads and evaluate obvious offsets. A poorly registered image as shown to the left in Plate 3 is not worth evaluating further. Note the direction of the offsets, check other regions to confirm the offsets, and return to GCPWORKS to redo the ground control point segment.

If horizontal and vertical roads align well in the first input window, switch to a flicker state with each image displayed 4,3,2 as RGB. Select 3-5 right-angle road intersections for evaluation. See Plate 2 for selection of road intersections. Flicker to the base image and zoom in on a selected intersection. Place the cursor at the center of the intersection, drawing two imaginary lines N/S and E/W to determine the exact location. Leaving the cursor in position, flicker to the newly registered image. Again, mentally draw two lines and determine the exact center of the new intersection. Do not move the cursor. Evaluate if the cursor is exactly on target, off by 0.5 pixel, 1.0 pixel, or > 1.0 pixel in both the x and y directions. See Plate 1 for evaluation of cursor location.

Complete a table as follows, with 12-20 road intersections across the scene. The table

will highlight regional or full-scene offsets. In this table each region and the scene as a whole meet the requirements of $\pm$ one pixel inter-scene alignment. The newly registered file is acceptable, and image processing can proceed. If, however, a region or the whole scene exceeds one pixel offset in either direction, then GCPWORKS, SMODEL and SORTHO must be repeated. Run CLR to reset the new file channel values to 0 before running SORTHO again. The table may be used to help guide the adjustment of the ground control points.

For example in a TM scene:

Region	x offset (pixel)	y-offset (pixel)
NW 1	0	0.5 -
NW 2	0.5 +	0.5 -
NW 3	1.0 +	0.5 -
NE 1	0	0.5 -
NE 2	0.5 +	0
NE 3	0.5 +	0.5 -
SE 1	0.5 +	1.0 -
SE 2	0.5 +	0
SE 3	0	0.5 -
SW 1	0.5 +	0.5 +
SW 2	0.5 +	0.5 +
SW 3	0.5 +	0.5 +

2.3 RADIOMETRIC AND ATMOSPHERIC CORRECTION

The following sections illustrate the EASI procedures used for radiometric calibration and atmospheric correction. Information from the header file is employed in the procedures. A bitmap is created first to mask the non-image pixels of the *ort.pix file. Typically the mask can be obtained by selecting all pixels in band 1 or

band 2 with values greater than zero. The mask is subsequently used for the creation of indices and other analysis. Limiting the processing to the image area of the file shortens processing time and eliminates the formation of anomalous features outside of the image area. The EASI thresholding procedure, THR may be use for creating the bitmap (Table 9). If necessary a similar mask may be created for the non-image area by setting the COMP parameter to "ON". The complement is used to fix anomalous data sometimes found in band 6.

Table 9. Bitmap creation with THR

2.3.1 TMRAD

Seven additional empty channels are added using PCIADD2. These are the output channels for the radiometrically enhanced bands, 8-14. TMRAD is an in-house EASI procedure which solves equations 1 and 2 in section 1.4.1. Sample parameters are set in Table 10. Latitude and longitude are given in decimal degrees, and

longitude is a negative value in the western hemisphere. TMSLOPE and TMBIAS may be obtained from the newer header files as Gain/10 and Bias/10, respectively. The solar constants (from Markham and Barker, 1986), and scale factors will change for different imagery and satellites. TEXT may be set to "stat" for a check on the output values (Table 11), which is also saved to a text file for reference.

2.3.2 RAYRAD - Rayleigh radiance

The Rayleigh correction factor is calculated with RAYRAD. Calculations may be found in Stumpf (1992). The procedure requires operator input as in Table 12, and produces output as in Table 13. The scale factor should be the same as that used in TMRAD.

Bands 1 - 4 are corrected by subtracting the Rayleigh values from each band respectively.

The Rayleigh values are the last column in Table 13, rounded to the nearest whole number. Values for bands 5 and 7 are insignificant, and for band 6, irrelevant. The model used to accomplish the subtraction is shown in Table 14. The bitmap is specified with "%2" and band 8 as "%8". Keep in mind that the radiometrically enhanced bands, 8 - 14, are equivalent to TM bands 1 - 7.

2.3.3 Dark object subtraction

Final atmospheric correction values are selected manually from a full-resolution display of bands 1 - 4, focused on areas of dark water. This step must be conducted, visually, AFTER the Rayleigh correction has been subtracted from the bands. The dark object subtraction itself may be conducted with EASI procedure, ARI, or with a model similar to the one in Table 14. The values shown in Table 15 are in the normal range for the region of the Big Bend coast. All channel descriptors (image layer histories) are renamed using MCD to more accurately describe the contents of the channel based on the pre-processing applied.

Table 15. Dark water values:

Channel 1: 16
Channel 2: 12
Channel 3: 8
Channel 4: 6

2.4 INDICES

Several indices are calculated at the final point in processing. An additional band is added to the .pix file for each index desired. Be sure to specify the correct band number when calculating an index. The examples below are based on the radiometrically enhanced data residing in bands 1-7. It is possible to protect previously processed image channels from accidental overwrites with the LOCK procedure.

2.4.1 Bitmap creation

A mask is employed to permit processing and modeling of image-only pixels. If not already done, the mask is created by selecting all pixels with a value of > 0 in TM band 1 or 2. The new bitmap segment is on at every image pixel and off at all non-image pixels. It is important that the operator check the band at full-resolution to ensure there are no zero values in the image area itself before running this procedure. The results can be checked afterwards on full-resolution display. Failure to check may result in missing data in the index channels. The mask is created by running THR as in Table 9. The mask allows the operator to run processes on image data only, maintaining values of zero in non-image areas of the file.

2.4.2 Vegetation Index

The vegetation index, NDVI may be calculated in the EASI procedure, RTR (Table 16). Alternatively, a model can be written to take the input channels 3 and 4 and write output NDVI to channel 8. Differences in NDVI between two years may range from ~-90 to +90. These values are re-scaled to range from 1 - 200.

EQUATION 7. EASI MODEL FOR NDVI

$$\%8 = 100 * (\%4 - \%3) / (\%4 + \%3)$$

2.4.3 Wetness Index

The wetness index may be calculated with EASI procedure, ARI (Table 17). It may also be run as an EASI model:

EQUATION 8. EASI MODEL FOR WETNESS INDEX

$$\%9 = \%5 - \%2$$

2.4.4 Thermal band 6 temperature

Temperature is calculated from TM thermal band 6 (Markham and Barker, 1986) to degrees Celsius plus 5. We add 5 degrees to account for near freezing temperatures which occasionally occur in the Big Bend region. The model is run from a file as follows:

EQUATION 9. EASI MODEL FOR TEMPERATURE IN CELSIUS

```
MODEL ON "/pathname/filename.pix
if %%2 = 1 %10 =
(1260.56/ln(60.776/(%6/100)+1))-268);
ENDMODEL
```

where segment 2 is a bitmap, masking image-only pixels.

2.4.5 Water reflectance

Water reflectance can be calculated with EASI procedure, ARI, (Table 18) or as follows:

EQUATION 10. EASI MODEL FOR WATER REFLECTANCE

$$\%11 = \%2 - \%4$$

2.4.6 Brightness

Brightness is merely TM band 2 with the appropriate adjustments for radiometric enhancement and atmospheric corrections. This is sufficient for comparison of brightness between scenes.

DATA STORAGE

I. Naming conventions

A. Image files:

Name: fltmN950402nlaps.pix

state (2) imagery type (2) region (1) date (yyymmdd) level (nlaps, ort, cor)

B. Report and text files:

Include date and 3-letter abbreviation of process with either .rep or .txt. Use .rep in the case of reports generated by EASI itself, and .txt for reports created by the operator.

II. CD-ROM Storage/Sets

Detailed information on CD-ROM storage levels is provided on each CD-ROM. In brief:

Set I contains the *nlaps file, a raw image file extracted from the original CD-ROM format and converted to a .pix format. The level I CD-ROM also contains the orbital and ground control point segments and models necessary for orthorectification of the imagery.

Set II contains the *ort file, a fully rectified image. The level II file has met accuracy standards both for inter-scene and coordinate plane map accuracies. The CD-ROM also includes all segments necessary for the rectification and all text files corresponding to the processing already completed.

Set III contains the *cor file, a radiometrically enhanced and atmospherically corrected image. The file includes four additional channels of data, vegetation index, wetness index, water reflectance and temperature. The level III CD-ROM also holds all text files pertaining to all levels of processing with summaries for ease in evaluation.

NOTES

One of the images below is misregistered, > 1 pixel on the x-axis. To identify a misregistered image, look for two parallel lines, red and blue, where a road should be. Well-aligned roads will appear white or will have a mottled pattern of colored pixels (mixed-pixel effect) which occupy essentially the same line.

Misregistered 1995 and 1985 images. 1995 band 4 is displayed in the red plane and 1985 band 4 in the blue plane. Note the parallel vertical lines at arrow #1 showing poor alignment in the x-axis. A similar but less distinct offset is apparent in the y-axis at arrow #2.

Properly registered imagery does not present the double red/blue lines indicative of misalignment. However, a newly-built or significantly altered road will stand out as a single red or blue line as indicated by arrow #3. Changes in land use and vegetation are also visible in this display as shades of red and blue.

Platc 1. Misregistration and acceptable inter-scene registration for 1985 and 1995

Cursor positioned at center of 1995 road intersection

Cursor at same pixel/line position in 1985 imagery

The road intersection in the older image is satisfactory. The cursor offset is less than one pixel. The road to the right appears to have been narrower in 1985 which accounts for the 1/2 line offset in the y-axis. The x-axis is well-aligned with less than 1/2 pixel offset. Note: we do not consider the smaller road to the left in this evaluation. It lacks clarity and does not approach the intersection at a right angle.

Plate 2. Comparison of right angle road intersection for inter-scene registration.

Plate 3. Preferred locations for inter-scene accuracy check, Chassahowitzka, FL, 1995.

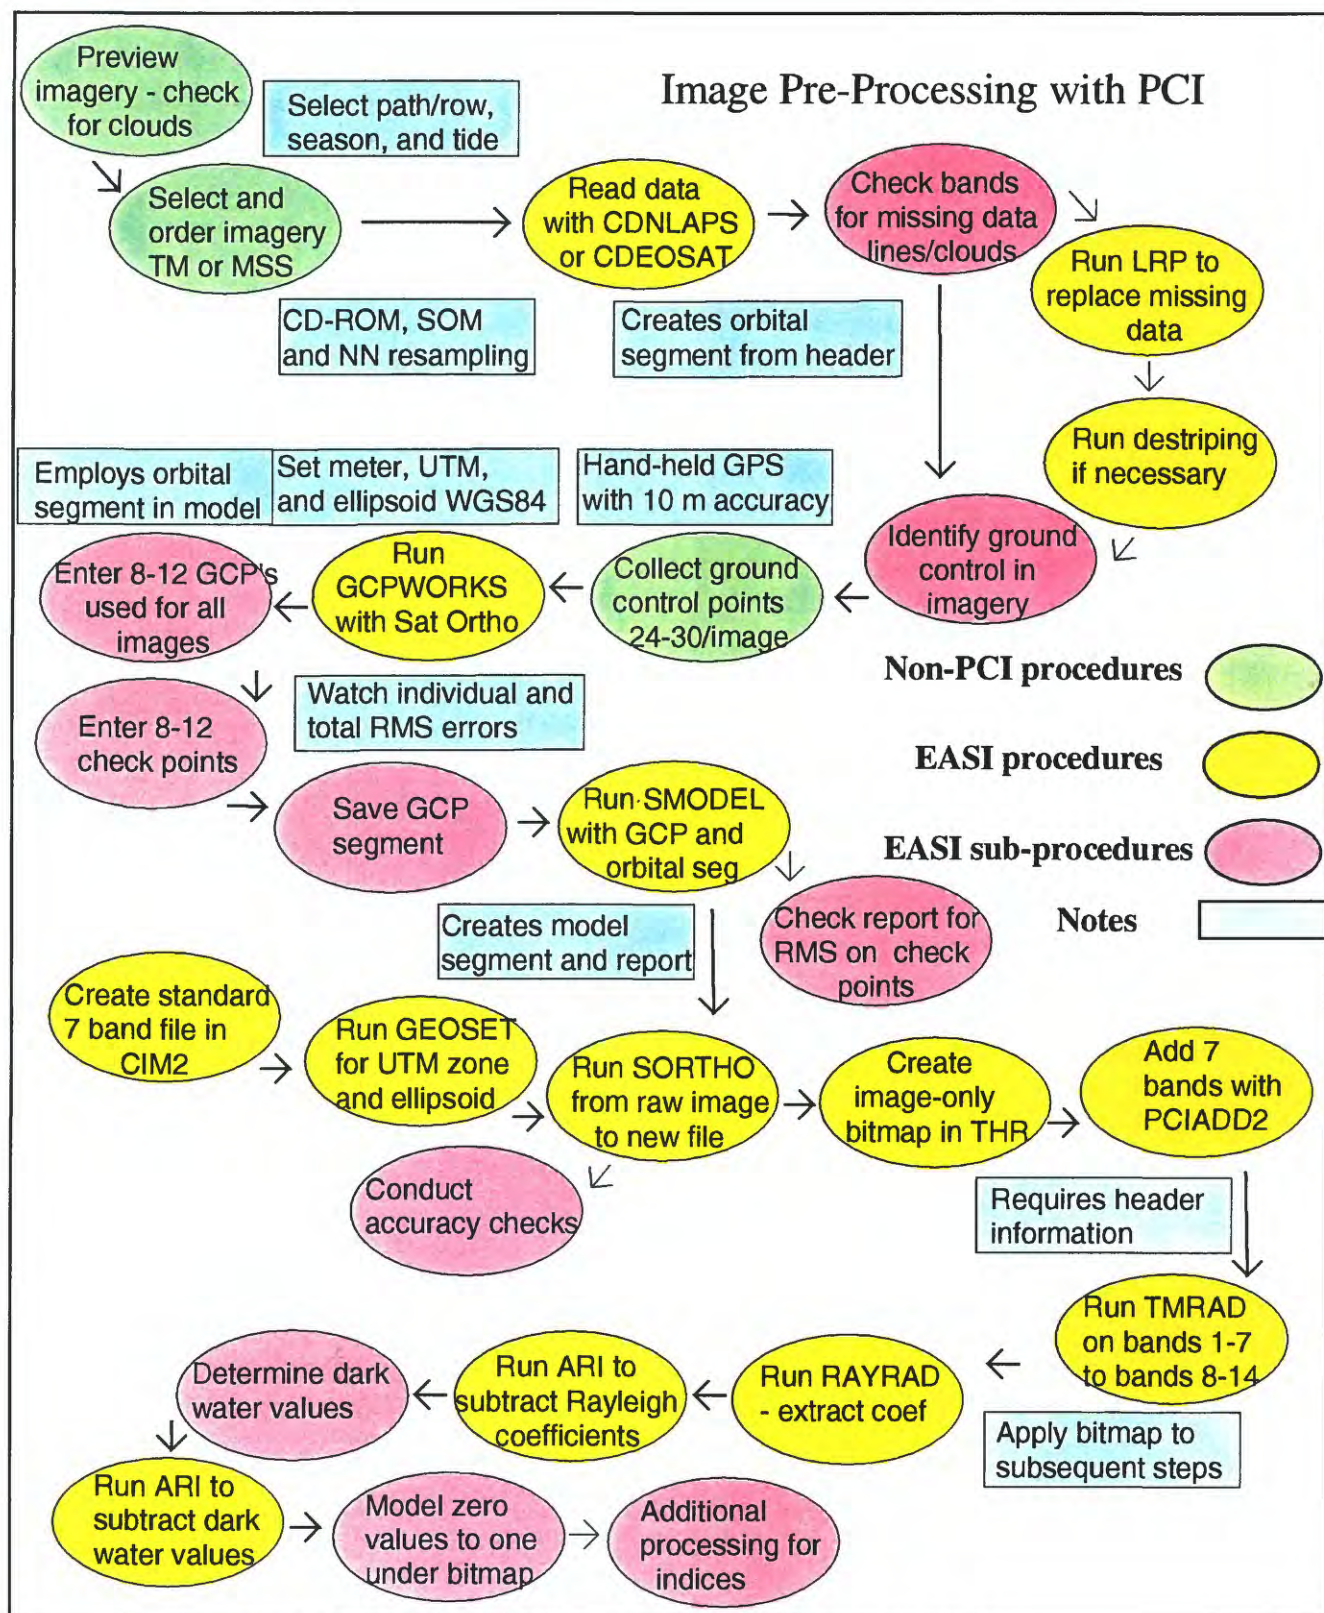

Plate 4. Flow chart for image pre-processing with PCI, Inc.

USDA is an equal opportunity provider and employer.

Foreword

This technical guide provides instruction and information on the development of the Terrestrial Ecological Unit Inventory (TEUI) for lands administered by the U.S. Department of Agriculture Forest Service. It provides a set of national standards, suggested methodologies, and a list of criteria for defining, describing, and classifying terrestrial ecological units and types.

The *TEUI Technical Guide* provides the standard for development of terrestrial ecological units at the landtype association, landtype, and landtype phase levels of the National Hierarchy Framework of Ecological Units (Cleland et al. 1997).

The *TEUI Technical Guide* is not intended to replace the correlation process of the National Cooperative Soil Survey (NCSS). It relies on the NCSS process to ensure quality control of all TEUI products, particularly soils data.

The following references may be useful in development of the TEUI and supplement the direction contained in this technical guide:

Chapter 1. TEUI Protocol Framework

1.1 Overview and Purpose

The purpose of this technical guide is to provide specific direction and guidance for conducting Terrestrial Ecological Unit Inventory (TEUI) at the landscape and land-unit scales. TEUI seeks to classify ecological types and map terrestrial ecological units (TEUs) to a consistent standard throughout National Forest System lands. The objectives, policies, and responsibilities for TEUI are contained in Forest Service Manual (FSM) 1940. U.S. Department of Agriculture (USDA) Forest Service policy dictates that ecological units be used in natural resource inventory, monitoring, and evaluation; in land management planning; and in making predictions and interpretations for management of National Forest System lands.

This guide is one among several recently established by the new FSM 1940 and Forest Service Handbook (FSH) 1900 series direction. This direction consolidates many outdated and redundant handbooks scattered throughout the directive system for all program areas responsible for conducting inventory and monitoring activities.

The new chapter in FSM 1940, “*Resource Inventories and Monitoring*,” establishes the management framework for all integrated inventories. It codifies the broad authorities, management objectives (results), policies, responsibilities (duties and delegations), and standards that govern how the agency designs, develops, tests, conducts, reports, uses, and evaluates resource inventory systems and data. The chapter requires field units to use the various technical guides intended to provide detailed instructions for conducting inventory and monitoring work (Connolly 2001).

The new FSH 1900 series, “*Resource Inventories and Monitoring*,” covers the data standards, procedures, practices, and other protocols that govern all our resource inventory and monitoring efforts. The handbook consolidates relevant inventory and monitoring direction from existing handbooks. It does not contain detailed instructions, templates, or other information contained in technical guides (Connolly 2001).

Figure 1.1 provides a graphical sketch of the relationship of manual and handbook direction to technical guides. The technical guides contain the detailed instructions and procedures on how to conduct specific inventory and monitoring activities. They are designed to be flexible so that updates and improvements can be made annually, or as needed based on best available science. All technical guides share the same overall format and outline as identified in the FSH 1900 series.

This guide contains three chapters and several appendixes on the following subjects:

- Chapter 1 provides an overview of TEUI concepts including background information, key concepts, and roles and responsibilities.
- Chapter 2 provides detailed information on conducting TEUI at the landtype association (LTA) level.
- Chapter 3 provides detailed instruction on conducting TEUI at the landtype (LT) and landtype phase (LTP) levels.
- Appendixes contain various field forms and detailed descriptions of data elements used in the protocols. Also included are a list of citations, a glossary, and other pertinent information.

Figure 1.1. Relationship of Forest Service manual and handbook direction to technical guides.

1.2 Background and Business Needs

1.2.1 Background

Ecological classification and mapping systems are designed to stratify landscapes at multiple scales so we can understand the arrangement, pattern, and capabilities of ecosystems. With this knowledge, we strive to make informed decisions about the management of public lands throughout the United States. Wertz and Arnold (1972) developed one of the first such systems in the Northern Rocky Mountain region in 1968. Their Land Systems Inventory (LSI) provided a method by which land with similar hazards and capabilities could be inventoried or categorized into repeating map units. A system

such as LSI was especially necessary after the National Environmental Policy Act of 1970 required an inventory of all forest lands related to the identified roadless areas. The Cascade Ranger District of the Boise National Forest was the first to implement LSI in 1968; by 1980, many LSIs had been completed throughout the region. In their 1972 publication *Land Systems Inventory*, Wertz and Arnold also introduced a hierarchy of ecological units including sections, subsections, LTAs, and LTs.

This hierarchy was later refined by Cleland et al. (1997) to become known as “The National Hierarchy of Ecological Units.” The Province of British Columbia (2001) developed a similar hierarchy land classification system in 1985 called the Ecoregion Classification System. At the detailed ecosystem level, ecosystem units are mapped using the Terrestrial Ecosystem Mapping (TEM) methodology. The TEM methodology stratifies the landscape into map units according to a combination of ecological features, primarily climate, physiography, surficial material, bedrock geology, soil, and vegetation (Province of British Columbia 1998). These concepts and methods of ecological mapping form the basis for the TEUI at the land unit and landscape scales. This technical guide borrows from these original principles and concepts, refining them yet again to meet more specific guidelines and data standards.

1.2.2 Business Needs

TEUI, in combination with other standard resource layers, provides the basis for selecting suitable areas for major kinds of land-use activities, identifying areas that need more intensive investigation, evaluating various land management alternatives, and predicting the effects of a given activity on resource health or condition. TEUI maps, data, descriptions, and management interpretations provide basic land capability information necessary for ecological assessments; project planning; watershed and landscape analysis; forest plan revisions; and implementation and monitoring of forest plans. The information provided can be used for activities such as assessing resource conditions, conducting environmental analyses, defining and establishing desired conditions, and managing and monitoring natural resources.

1.3 Key Concepts

To implement ecosystem management, we need basic information about the nature and distribution of ecosystems (Cleland et al. 1997). An ecosystem consists of a community of organisms and their physical environment, which together form an interacting system or unit, and occupy an identifiable space (Lincoln et al. 1998, SRM 1998). TEUI includes classification and mapping of ecosystems. Ecological classification provides basic information about the nature of ecosystems and mapping depicts the distribution of ecosystems.

TEUI endeavors to classify and map ecosystems based on biotic and abiotic factors that comprise the physical environment. These factors are referred to as landscape elements and are illustrated in figure 1.2, which diagrams the influence of landscape elements on each other. The diagram is arranged in four levels. The elements at the top (bedrock geology, regional climate, and geomorphic processes) are largely independent variables (Daubenmire 1978). The elements in each level of the diagram are influenced by the elements in the levels above; the farther apart the levels, the less direct the influence.

If a close relationship is established between independent and dependent variables, then the independent variables may be useful predictors of the dependent variables (Webster and Oliver 1990). In figure 1.2, the variables of bedrock, geomorphic process, and regional climate do not typically have a close enough relationship with soil and PNV to be useful predictors (as illustrated in figure 1.2 by their distance from the soil and PNV elements). Landform, surficial geology, local climate, and morphometry more directly influence soil and PNV development, and thus are typically better proxy indicators of soil and vegetation, and consequently ecological types. The relative importance of these factors varies across ecoregions and may vary within an inventory area. TEUI requires determining and documenting the importance and relationship of these factors.

Figure 1.2. General relationships of landscape elements.

1.3.1 The National Hierarchy Framework of Ecological Units

The National Hierarchy Framework of Ecological Units (hereafter referred to as the National Hierarchy) is a land classification hierarchy that provides a framework for developing TEUs at continental to local scales. Since this is a nested hierarchy, finer-level classes are descendants of higher-level classes and have their characteristics. The hierarchy framework is organized into four “planning and analysis” scales, which are described by eight levels of ecological units. The levels in the National Hierarchy at each planning scale are described below (Cleland et al. 1997) and represented in table 1.1. This technical guide, however, only focuses on the landscape and land-unit scales. Hence, we will not discuss standards and methods for ecoregion and subregion ecological inventories.

Ecoregion

The ecoregion scale comprises three levels of ecological units (domain, division, and province), which are recognized by differences in global, continental, and national climatic regimes and gross physiography.

Subregion

The subregion scale comprises two levels of ecological units (section and subsection) characterized by combinations of regional climate, geomorphic process, topography, and stratigraphy.

Landscape

The landscape scale contains the LTA level. The LTA depicts broad patterns of soil families or subgroups, potential natural vegetation (PNV) series, and, on occasion, show successional dynamics. Top-down delineation uses other abiotic factors in addition to, or in lieu of, soils and PNV. These factors may include dominant geomorphic process, landforms, surficial and near-surface geologic formations, and local climatic effects. The relative utility of these elements for delineating the LTA varies with ecological province. The LTA can also be designed and delineated bottom-up by aggregating the LT based on the above factors.

Land Unit

The land-unit scale comprises two levels of ecological units (LT and LTP) characterized by repeating patterns of one or more ecological types. LTs and LTPs represent the largest scale (land unit) and most detailed levels of the National Hierarchy.

LTs are subdivisions of LTAs. They can be used to refine top-down LTAs in which they occur based on comparison of their component ecological types and incorporation of their finer scale delineations. Composition of LTs can be summarized to describe the composition of LTAs.

Table 1.1. *Suggested level of detail used for classification and mapping at the landscape and land-unit levels of the National Hierarchy (modified from Cleland et al. 1997).*

Planning and analysis scale	Ecological unit levels	Geology	Geomorphology	Soil	Potential natural vegetation
Landscape	Landtype association (LTA)	Primary lithology or groups of secondary lithology	Geomorphic process and subprocess types	Great group and subgroup	Series and subseries
Land unit	Landtype (LT)	Secondary lithology	Landforms, element landforms, and morphometry	Subgroups, families, and series	Subseries and plant associations
	Landtype phase (LTP)	Secondary lithology	Landforms, element landforms, and morphometry	Series and phases of series	Plant associations and plant association phases

1.3.2 Classification, Map Unit Design, and Map Unit Delineation

The purpose of TEUI is to classify ecosystem types and map land areas with similar capabilities and potentials for management (Cleland et al. 1997). Because of their management significance, soils and vegetation, including historic and potential, form the primary criteria for classifying ecosystems and designing ecological map units at finer scales. Other landscape elements are driving factors in the development of soils and vegetation and are used primarily as delineators of ecological units at these scales. In areas where geologic hazards limit management options, bedrock and/or surficial geology may become classification and design criteria.

Relationship of Classification and Mapping

Soil scientists and vegetation ecologists have long sought to have their respective products serve as the basis of fine-level units (Nowacki 2003).

Soil science has emphasized soil classification and mappings of soil components on the landscape, while vegetation ecology has focused on classification using multivariate methods. TEUI is an attempt to combine the strengths of these two disciplines and more fully integrate climatic and geologic factors to more effectively classify and map ecosystems.

Multivariate analysis is also helpful in developing ecological classifications when relationships between PNV, existing vegetation, soils, and other landscape elements are obscured by other ecological or biological phenomena. These may include climate change and vegetation inertia (Collinson 1988, Pielou 1991), changes in a species indicator value because of genetic variation and geographic changes in associated species (Mueller-Dombois and Ellenberg 1974), and differing rates of soil and vegetation development following large geologic or geomorphic events (Pielou 1991). Multivariate analysis can also focus on specific soil properties instead of soil taxonomy, which still has many inherent agricultural biases (USDA Soil Conservation Service 1994).

The above issues make multivariate analysis essential for ecological classification at the LT and LTP levels. It can also be useful in developing ecological classifications for bottom-up LTAs.

Cleland et al. (1997) indicate that at coarse scales ecosystem landscape elements can be analyzed and mapped separately, and then combined using the Geographic Information System (GIS) to produce ecological unit maps. At fine scales, landscape elements are evaluated simultaneously to classify ecological types, which are then used to design ecological map units. This process is used because of the importance of biotic factors, the level of discernible detail, the number of landscape elements, and the number of variables used to characterize elements progressively increase at finer scales (Cleland et al. 1997).

Map Unit Delineation

PNV and soils share an important property in relation to mapping. Neither can generally be seen on aerial photos, satellite imagery, or digital elevation maps. Soil cannot be seen because it is underground. PNV often cannot be seen because existing vegetation is usually not at potential because of natural or human disturbances. Moreover, it can be difficult to identify plant species other than trees on photos or imagery.

Because soils and PNV cannot be delineated directly, we rely on other landscape elements, as surrogates, such as landform, morphometry, and surficial geology in combination with existing vegetation to map them. Those elements serve as map unit delineation criteria, but not necessarily as map unit design criteria. Map unit design involves deciding which elements we want to depict spatially and how detailed, both thematically and spatially, that depiction will be. Map unit delineation criteria are selected to implement the map unit design.

Ecological Classification

An ecological type is a category of land with a distinctive combination of landscape elements, differing from other types in the kind and amount of vegetation it can produce and in its ability to respond to management actions and natural disturbances. The ecological classification process is used to define, quantify, and document relationships among abiotic landscape elements, existing vegetation types, and PNV types. These relationships are used to develop a classification of ecological types. Different combinations of landscape elements that do not differ in PNV, successional dynamics, or management capabilities do not always constitute separate ecological types.

Traditionally, landscape elements have been classified separately. Some classifications deal with qualitative attributes, while others emphasize quantitative attributes. Classification of ecological types requires integration of numerous qualitative and quantitative attributes. The methods of multivariate analysis are best suited for this task. However, use of an interdisciplinary team to select analysis variables is required to ensure the process is objective.

Gauch (1982) states that, “multivariate analysis is the branch of mathematics that deals with the examination of numerous variables simultaneously. The need for multivariate analysis arises whenever more than one characteristic is measured on a number of individuals, and relationships among the characteristics make it necessary for them to be studied simultaneously. The purpose of multivariate analysis is to treat multivariate data as a whole, summarizing the data and revealing their structure.” Put another way, multivariate analysis is used “to make large, unwieldy masses of multivariate field data comprehensible and interpretable” (Pielou 1984).

In summary, classification of ecological types organizes knowledge about relationships between ecosystem elements and the significance of those elements and relationships for land management. This knowledge can be used to design ecological map units that “identify land . . . areas at different levels of resolution that have similar capabilities and potentials for management” (Cleland et al. 1997). Ecological classification can help determine both the thematic and spatial resolution needed to address management issues. Once the detail level of the map units has been determined, the relationships documented in the ecological classification can be used to select delineation criteria for those map units. Thus, classification of ecological types can greatly improve both map unit design and map unit delineation.

1.3.3 Geology

Geology is an important element of TEUI because it is one of the abiotic elements and the foundation for the biotic elements. Geology greatly influences soil formation, provides nutrients for plant uptake, and often affects water transport and availability. Geologic information is essential for predicting the occurrences and distributions of ecological types. The geology element of TEUI should be documented during the mapping and classification procedures. Initial data should be collected as part of the literature search step during the initial steps of TEUI.

The primary sources for existing geologic data and maps are the U.S. Geological Survey (USGS) and State geological surveys. Local university geology departments may also have an archive of unpublished mapping for the inventory area.

Bedrock and Surficial Geology Classification and Description

Both bedrock and surficial geology are described for each ecological type. Bedrock data collection will conform to the standards described in *Geology in the Field* (Compton 1985), sections 1-4, 3-1, 3-2, 3-5, 3-6, 5-1, 5-2, and 5-3 with additional guidance from chapters 6 and 7. Surficial materials data collection will conform to the *Soil Survey Manual* (1993, 73–80).

Describe and classify bedrock geology by lithology (i.e., rock class or name) using *Classification of Rocks* (Travis 1955). In addition, if the bedrock's stratigraphy (i.e., formation or member, and geologic age) is known or suspected to correlate with ecosystem character and function, it must also be determined.

Lithology and Surficial Materials

TEUI uses primary and secondary lithology as defining elements. Primary lithology is the class to which a rock belongs: igneous extrusive, igneous intrusive, sedimentary, or metamorphic. Secondary lithology is the specific rock type (e.g., basalt, granite, sandstone, gneiss); each implies one and only one primary lithology. If TEUI is composed of many rock types (e.g., a mix of basalt, andesite, and tuff), it may be best to classify at the primary lithology level (e.g., igneous extrusive).

Bedrock characteristics (i.e., texture, weathering, chemistry, fracture interval, competence, structure type, azimuth, and inclination) will be described for those integrated plots where bedrock is encountered and for “stops” on geologic traverses. See appendix D, Geology and Geomorphology Form.

Surficial materials are in the “unconsolidated” primary lithology class. They are defined as nonlithified deposits lying on bedrock or occurring on or near the Earth’s surface. Surficial materials are characterized by their depositional environment (“kind”) and the rock type (secondary lithology) from which they came (“origin”). Some examples: glacial till from granite, alluvium from sedimentary rocks, landslide deposit from limestone, and volcanic ash of basalt composition. Another important factor in characterization is the material’s texture (e.g., bouldery, sandy, clayey). Texture terms are applied during the integrated-plot description. Multiple surficial materials, if present, should be noted (e.g., loess, over colluvium, over residuum). See appendix D.

Stratigraphy

According to Salvador (1994), “Stratigraphy is the description of all rock bodies forming the Earth’s crust, and their organization into distinctive, useful, mappable units based on their inherent properties or attributes. It includes the classification, naming, and correlation of these units to establish their relationship in space and succession in time.” At the land unit scale, this description usually consists of a geologic age and a stratigraphic-unit name followed by a specific rock type, or by the term “formation” if the unit contains more than one rock type. Formations may be divided into “members” or aggregated into a “group.”

When a formal stratigraphic map unit exists, it may be used to help describe a TEU. The primary sources for stratigraphy are published geologic maps that conform to the USGS Code of Stratigraphic Nomenclature. Refer to the legend and geologic map unit descriptions to identify the geologic time units and formations in an area.

Stratigraphic names, descriptions, ages, and references should be included in the TEUI manuscript, and incorporated in regional code tables of the corporate database. It is important to note that variations in lithology and thicknesses of specific stratigraphic units may exist within a survey area, or in regional settings. Therefore, one description of a particular lithology may not represent those strata across a survey area.

1.3.4 Geomorphology

The primary reference and data standards for the geomorphology components used in the development of TEUI are contained in the USDA Forest Service publication *A Geomorphic Classification System, version 1.4* (Haskins et al. 1998).

Geomorphology, as described in the above publication, includes three primary components:

- 1. Geomorphic Process.** The dominant internal or external geologic force that has interacted with the existing geologic structural framework to shape the Earth’s surface.

-
2. **Landform.** “Any physical feature of the Earth’s surface, having a characteristic, recognizable shape and produced by natural causes” (Bates and Jackson 1980, 1987).
 3. **Morphometry.** “The measurement and mathematical analysis of the configuration of the Earth’s surface and of the shape and dimensions of landforms” (Bates and Jackson 1980, 1987).

Landform, in this classification hierarchy, is directly linked to geomorphic process. Process is implied by selection of a particular landform. A landform choice, therefore, carries with it the process that was responsible for its development (reflected in the list of valid values found in appendix D).

Morphometry is used to quantify the land surface and describe further the variability in landforms. It can be used to predict changes in slope hydrology, soils, and plant communities. The following measurements or characterizations are elements of morphometry: relief, elevation, aspect, slope gradient, slope position, slope shape, slope complexity, landform width, dissection frequency, dissection depth, drainage pattern, and drainage density. Not all parameters are applicable at all levels. In addition, these parameters can be expressed as ranges of values, averages, or means. See appendix D for definitions.

Geomorphic Process

The appearance of a landscape is a result of the geomorphic processes that have shaped it in the past, and that continue to shape it today. The history of a landscape may be complex, with many geomorphic processes overprinting one another. This overprinting occurs when two or more dissimilar geomorphic processes have operated on an area at different times because of the influences of climatic change and/or tectonics. Such complexity is documented using geomorphic generation, which identifies the status of all the processes that operated on any given location.

The Great Sand Dunes National Monument in southern Colorado represents an easily understood example of landscape (and landform) correlation with generations of geomorphic processes. The sand dunes occupy a portion of the still-active Rio Grande rift along the margin of the San Luis Valley, which was formed by tectonic and fluvial geomorphic processes. The present day landscape, however, is dominated by eolian (dune-forming) processes.

Landforms may be characteristic of a combination of geomorphic processes; for example, talus forms by weathering, erosion, and downslope movement. Landforms also may be characteristic of more than one geomorphic process. Canyons form through fluvial processes but also are typically characterized by mass wasting (landslides and rock falls).

Determination of the geomorphic generation of each landform will identify the relationship between the landforms and the status of the process, which formed or continues to form the landforms. The appropriate terms used to identify geomorphic generation are active, dormant, and relict.

Appendix D lists the valid values to be used in TEUI classification and characterization.

Use in Mapping

The *National Soil Survey Handbook* (NSSH), part 627.02, (USDA NRCS 2003b) describes the delineation of major landform units and landform components as a preliminary procedure in field mapping. The next step is the identification, description, and classification of the kinds of soils associated with the landform components. The *NSSH* (USDA NRCS 2003b) states that because “soil patterns commonly coincide with major landforms and individual soils with individual landform components, the objective of identifying and understanding the relationship between landforms and soils is to enable a soil scientist to predict the kind of soil on the landform.”

The relatively larger scale of the landform component is often useful for stratifying the landscape into segments having similar climate, physiography, geomorphology, and parent materials from which further predictable delineations of geology, soils, and PNV can be made.

Application

In complex landscapes, the landform often serves as the primary delineation criterion for identifying TEUs. Landforms and morphometry are important in defining the way water and materials translocate over and through watersheds. Landforms and morphometry are important for influencing watershed storm precipitation response, sediment routing, erosion rates and volumes, groundwater and materials storage and recharge, and duration and intensity of solar radiation.

Landforms and their associated geology also enable us uniformly and consistently to predict and interpret properties such as hydrologic behavior, slope stability, and sediment storage, for assessing land-use potential, capabilities, limitations, and hazards.

Geomorphology often changes where natural patterns of the landscape change. Consideration of whether a change is significant and should be delineated separately from surrounding landforms depends on many factors. For example, changes in morphometry may signal a significant coincidental change in geomorphology.

An understanding of geomorphic processes and their resultant landforms provides the mapper the ability to predict and extrapolate TEUI element distributions.

1.3.5 Soil

The soil element of an ecological type must be described, classified, and characterized according to the standards defined in the *Soil Survey Manual* (USDA NRCS 1993) and the *NSSH* (USDA NRCS 2003b).

Characterization

Document soil properties (both chemical and physical) that are the basis for classification. Include soil properties that significantly influence ecosystem character and function. Describe and establish the range of significant soil properties. It may be desirable to phase those soil properties that influence the character or interpretation of each component.

Characterization should be based on observed ranges from all samples collected for that ecological type. Characteristics not observed but estimated or derived (such as available waterholding capacity) should be designated as such and methods documented.

Soil Classification

A national soil classification system provides the definitions and nomenclature necessary for classifying soil. The official soil series descriptions provide definitions, procedures, and nomenclature for establishing soil series. See the *NSSH* (USDA NRCS 2003b), Part 614. Classify the soils according to the most recent edition of *Keys to Soil Taxonomy* (USDA NRCS 2003a). Classify soils at the soil series or family level of soil taxonomy. For highly variable areas, such as riparian areas, disturbed areas, or steep slopes, classify soils at a higher level of soil taxonomy.

Soil classification is used to provide the following elements:

- A connotative naming system that enables those users familiar with the nomenclature to recognize selected properties of soils.
- A means for understanding the relationships among soils in a given area and among different areas.
- A means of communicating concepts of soil and soil properties.
- A means of projecting experience with soils from one area to another.
- Names that can be used as reference terms to identify map unit components.

Application

The information assembled about soils in the TEUI map unit descriptions and associated data tables are used to predict or estimate the potentials and limitations of soils for many specific uses. The predictions serve as a basis for judgment about land use and management for areas ranging from small tracts to regions of several million acres. These estimations must be evaluated along with economic, social, and environmental considerations before recommendations for land use and management become valid. Many standard and locally defined interpretations are available from the TEUI (see chapter 3, tables 3.6 and 3.7).

1.3.6 Vegetation

The vegetation element of an ecological type must be described, classified, and characterized. Historic vegetation, disturbance regimes, existing vegetation, PNV, and state and transition models are typically documented for each ecological type. Guidelines for classifying and mapping ExistingVegetation are described the *Existing Vegetation Classification and Mapping Technical Guide* (Brohman and Bryant 2005).

Use in Mapping

Existing vegetation is often used to delineate ecological map units, however, care must be taken, as existing vegetation does not always reflect historic or potential vegetation. Historic vegetation, disturbance regimes, and potential vegetation are typically not mapped because it cannot be readily identified on aerial photography. Rather, the relationship between existing vegetation and association of landscape elements are used to predict these important vegetation characteristics. The text that follows gives guidelines for determining historic vegetation, disturbance regimes, PNV, and developing state and transition models.

Historic Vegetation and Disturbance Regimes

As primary producers of living tissue (biomass), vegetation is a fundamental component of ecosystems. Human and animal existence and welfare are ultimately derived from vegetation. Humans have manipulated vegetation over the course of thousands of years for food and fiber production, and continue to do so. Since resource management largely involves vegetation alteration in one-way or another, successful land stewardship is predicated on understanding various aspects of vegetation: its composition, structure, dynamics (successional changes), and potential.

The Earth's vegetation is a complex patchwork, reflecting an amalgamation of abiotic and biotic interrelations across time and space. Vegetation communities are a result of

interaction within and among (1) biota (species evolution, adaptation, gene flow, physiological traits, competitive abilities, and resiliency; herbivory), (2) physical environments (e.g., climate, topography, geology, soils), and (3) disturbances (wind, fire, insects, disease, etc.) including human activities. The inherent complexities of vegetation dynamics (e.g., how vegetation originated in an area and how it might change in the future) require several lines of inquiry for adequate understanding. These core components include historic vegetation, disturbance regimes, existing (current) vegetation, and PNV. All are important for understanding vegetation patterns and processes at various spatial and temporal scales and are essential for vegetation management, particularly for preparing desired future conditions, silvicultural prescriptions, and ecological restoration plans.

Historic Vegetation

Vegetation communities are as much a product of past events as they are contemporary processes; thus, ecologists who overlook the past are likely to misinterpret the present (Whitney 1994, 4). Indeed, “stepping back to look forward” is a rationale way of understanding the historical milieu that has led to current vegetative conditions (Foster 1998). Not only do stand histories help explain the origin of current forest conditions (Carvell 1986), but knowledge of past or historic vegetation (compositions, structures, dynamics) proves crucial in the restoration of ecological systems that have been negatively altered by human or natural disturbances. Recent compilations by Fulé et al. (1997), Balee (1998), Swetnam et al. (1999), and Egan and Howell (2001) provide overarching principals of historical ecology and its relevance to resource management and ecosystem restoration.

Trends in historic vegetation can be displayed over long time periods spanning thousands of years. The relevance of ecological data diminishes the further back in time one goes due to increasing differences in ecological conditions (e.g., climate, disturbance regimes, species distributions). Thus, a more narrow, ecologically relevant time period is sought in order to capture past vegetation conditions for land management objectives (e.g., document native communities, assess historic vegetation changes; set ecological restoration goals). A 500-year period immediately preceding European settlement is a reasonable time period for reference conditions. By focusing on vegetation characteristics (composition, structure, and dynamics) of this time period, we document those conditions immediately prior to major landscape changes wrought by European settlement (Whitney 1994). Historic vegetation can be reconstructed using a variety of approaches, either singly or, more robustly, in combination (Noss 1985; Whitney 1994, chapter 2).

- 1. Historical Accounts and Notes.** Written observations (chronicles, journals, diaries, newspapers, etc.) from early explorers, surveyors, and settlers serve as fundamental descriptions of past vegetation. Examples of early descriptive accounts for interpreting original forests include Bromley (1935, southern New England) and Nelson (1957, Georgia).

-
- 2. Early Land Surveys.** This probably represents the best and most frequently used information source for reconstructing pre-European vegetation, especially in forested areas. There are two principal types of land surveys conducted in the United States.
- a. The metes and bounds system was the primary land survey method in Colonial America. This system led to indiscriminate and irregular divisions of the land, often shaped in deference to the owner desires, using trees, rock outcrops, post and stone monuments, river and stream courses, and ridgelines as boundary markers (Ernst 1979, Abrams and Ruffner 1995, Black and Abrams 2001a). Representative excerpts from early land surveys can be found in Spurr (1951). Because it was an unintentional vegetation survey, a number of biases and errors may occur in the tree data (Whitney 1994, Black and Abrams 2001a). Witness-tree data should be used cautiously because of known biases of corner tree selection, including economic value, ease of inscription, size, vigor, longevity, and age. Where it exists, other ancillary data, such as trees marked for road surveys, can be used to assess for bias (Whitney 1994, Burgi and Russell 2000). Often pre-European forest composition is reconstructed using simple tallies of corner trees. These data, in turn, can be compared to contemporary vegetation surveys to depict historic vegetation changes (Nowacki and Abrams 1992, Abrams and Ruffner 1995) or correlated with soil-site factors to document species-environmental relations (Black and Abrams 2001a). The tree data are not as conducive to statistical analysis as later systematic (rectangular) land surveys and thus are less reliable in quantifying pre-European settlement forest conditions.
 - b. Through the Land Ordinance of 1785, Congress established the rectangular system for surveying public lands (Stewart 1935, Ernst 1979, White 1991). Designated the General Land Office (GLO) Survey, the majority of the United States was surveyed via this system, except for the original 13 States, Kentucky, Tennessee, Vermont, and Texas (Ernst 1979). This land survey method consists of a nested grid consisting of townships (36-mile squares), sections (36-mile squares; 360 acres), and quarter sections (9-mile squares; 90 acres). Surveyors were instructed to blaze and inscribe two to four “bearing” or “witness” trees (one per compass quadrant) at quarter-section corners. “Line” trees encountered between corners along survey lines were also marked. Pertinent ecological data recorded from these trees, known collectively as “witness trees,” include species, diameter, and distance to the survey corner.

The systematic collection of witness-tree data fosters the use of statistical analyses for forest reconstruction and the detection of possible surveyor biases. The proper

use and limitations of witness-tree data are thoroughly summarized by Hutchinson (1988), Schulte and Mladenoff (2001), and Whitney and DeCant (2001). Statistical procedures used to assess for surveyor bias and variability have been proposed by Bourdo (1956), Delcourt and Delcourt (1974), and Manies et al. (2001). Due to landscape heterogeneity and data-point-density limitations, caution needs to be employed when using GLO survey data to recreate pre-European settlement vegetation at fine scales (i.e., less than several townships or areas less than 10^4 ha) (Manies and Mladenoff 2000). GLO survey data are best compiled to form vegetation units of a quarter mile (160 acres) to 1 mi² (640 acres) (Delcourt and Decourt 1996). This unit-size is reasonable for assessing post-European settlement changes at the landscape scale.

GLO survey data often have been extrapolated spatially onto the landscape by coupling it to soil surveys forming discrete forest type maps (see Shanks 1953, Lindsey et al. 1965, Crankshaw et al. 1965, Siccama 1971). Substantial improvements in spatially projecting GLO survey data have been made by employing fuzzy logic to produce superior forest type classifications and maps (Brown 1998). Qualitative GLO survey data provided by written descriptions of vegetation (and disturbance patches) along transects between corners can be used to collaborate quantitative results from bearing-tree data (Nowacki et al. 1990, table 7).

GLO Survey provides forest structure data to reconstruct the spatial arrangement and size-class distribution of trees, although again some sampling bias may exist (Bourdo 1956). Statewide maps of pre-European settlement vegetation composition exist for Indiana (Lindsey et al. 1965), Michigan (Veatch 1959), Minnesota (Marschner 1974), Ohio (Sears 1925, Gordon 1969), and Wisconsin (Finley 1976). Digital pre-European settlement maps for the Upper Great Lakes States are available on the Internet (<http://www.ncrs.fs.fed.us/gla/>). By integrating past survey data with land-use histories and current inventories, important shifts in vegetation composition and structure can be documented and explained (Whitney 1990, White and Mladenoff 1994, Abrams and Ruffner 1995). Silbernagel, Chen, et al. (1997) and Silbernagel, Martin, et al. (1997) have done a particularly superb job of integrating pre- and post-European settlement vegetation and land-use data with a spatial hierarchy to describe historic vegetation changes within a landscape context.

3. **Photography.** Nothing is more self-evident than providing visible portrayals of the past. As the old adage goes: “A picture is worth a thousand words.” Through repeat photography, vegetation changes over time can be sequentially documented and catalogued (Progulske 1974, Gruell 1983, Gary and Currie 1977, Reid et al. 1980, Strickler and Hall 1980, Skovlin and Thomas 1995).

4. Statistical Series.

- a. Land-use data (Marks 1942, Brender and Merrick 1950, Moore and Witham 1996, McWilliams et al. 1997).
- b. Timber, agricultural, and fuel accounting books (Reynolds and Pierson 1942, Dinsdale 1965, Gates 1976, Johnson and Gerland 1996, Simard and Bouchard 1996).

5. **Studies of Primary, Original, or Old-Growth Forests.** In certain areas where disturbance regimes are equivalent to that of the past, present-day vegetation compositions and structures may closely resemble pre-European settlement conditions. Examples of this direct method include boreal forests of Minnesota (Heinselman 1973), conifer-northern hardwoods of Upper Michigan (Frelich and Lorimer 1991), and spruce-hemlock forests of southeast Alaska (Nowacki and Kramer 1998). See Nowacki and Trianosky (1993) for a listing of published old-growth manuscripts covering the Eastern United States.
6. **Archaeological Evidence.** Archaeological sites can provide an ethnobotanical record of surrounding local vegetation (Delcourt et al. 1998). There are known restrictions since materials reflect human collections of plants used for food and medicinal purposes. Tankersley et al. (1996) provides a good example of using archaeological information to determine a segment of prehistoric vegetation.
7. **Paleoecological Data.** This data provides long-term vegetation trends, sometimes spanning tens of thousands of years, and includes pollen, macrofossil, and charcoal/sediment analyses (Wright 1974, Clark 1990, Foster and Zebrek 1993, Motzkin et al. 1993, Russell et al. 1993, Rhodes and Davis 1995, Baker et al. 1996, Clark and Royall 1996, Kearsley and Jackson 1997, Delcourt et al. 1998, and Pitkanen 2000) and physical evidence of trees buried *in situ* (Pregitzer et al. 2000).
8. **Soil Phytoliths.** Phytoliths are “jewels of the plants world,” representing hydrated silica imprints of plant cells (Fredlund 2001). These microscopic fossils can be used as a means to reconstruct past vegetation (Birkeland 1974). Due to differences in silica content (grasses are high in silica content whereas most tree leaves are low), some plants may be over represented while others under represented (Fredlund 2001). Due to their enhanced ability of silica production, grasslands are the best biomes for using this line of evidence.

9. Traditional Ecological Knowledge/Native Oral Histories. Although downplayed or overlooked in the past, the application of traditional ecological knowledge for understanding past conditions is rapidly gaining momentum (Kimmerer 2000). A full issue of *Ecological Applications* (October 2000) is dedicated to this line of research (Ford and Martinez 2000).

Disturbance Regimes

The role of natural disturbance in shaping forest composition, structure and function is recognized globally (Pickett and White 1985, Attiwill 1994, Reice 2001). Many forest characteristics are better understood as responses to different kinds of disturbances rather than the result of successional change towards equilibrium (Brubaker 1987). As such, disturbance ecology is extremely relevant to resource management, providing an important conceptual framework for understanding our environment (Engstrom et al. 1999). Natural disturbance alter ecosystem characteristics that matter to managers, including species composition and structure, biodiversity, resource productivity, and incidence of disease. Managers themselves respond to and introduce disturbances all the time. Since disturbances have so profoundly influenced the biotic portion of ecosystems (e.g., species evolution and adaptations; vegetation compositions and structures), it stands to reason that disturbance regimes can be used as a template to design our management activities upon – that is, emulating those processes that have led to native biodiversity and other ecological attributes (Attiwill 1994, Swetnam et al. 1999). Silviculture stands to benefit substantially through emulating natural disturbance regimes (Kimball et al. 1995, Walker et al. 1996, Nowacki and Kramer 1998, Cissel et al. 1999, Bergeron et al. 2002, Seymour et al. 2002), although there are caveats to consider (Patch 1998, Lorimer 2001). This topic is thoroughly explored in a special issue of *Forest Ecology Management* (Mitchell et al. 2002). Disturbance ecology includes human effects (land-use histories) that have influenced today's vegetation characteristics (Brender 1974, Whitney and Somerlot 1985, Christensen 1989, Glitzenstein et al. 1990, Orwig and Abrams 1994). Lorimer (1985; list modified below) itemizes a variety of quantitative methods for ascertaining forest disturbance history.

1. External Physical Evidence

- a. Fire scars. Exposure to recurrent fire causes the scarring of tree boles, thus forming a record of past disturbance events in pyrogenic systems (Buell et al. 1954, Johnson 1979, Dieterich 1980, Guyette and McGinnes 1982, McBride 1983, Swetnam 1993, Gutsell and Johnson 1996, Loope and Anderson 1998). Fire periodicity and extent can be reconstructed using fire-scar data.

-
- b. Forest floor. Physical evidence can be used to trace developmental histories of forest stands (Henry and Swan 1974, Oliver and Stephens 1977).
 - c. Paleoecological data. Pollen, macrofossil, and charcoal assemblages in bog and lake sediments can be used to reconstruct past disturbance regimes (Clark 1990, Larsen and MacDonald 1998). Armed with pollen, charcoal, and ethnobotanical data, Delcourt et al. (1998) established strong linkages among prehistoric human occupation, plant domestication, and increases in local fire.

2. Demographic Evidence

- a. Tree-age and size distributions and time-since-disturbance maps. See Heinselman (1973), Johnson and Larsen (1991), and Reed et al. (1998) for examples.

3. Physiological Evidence

- a. Radial growth patterns. Tree rings are a natural data storage system containing valuable ecological and historical information (Creber 1977, Banks 1991). In dense temperate forests, tree-ring growth is often linked to competition for growing space/resources rather than climatic factors (Phipps 1982, Blasing et al. 1983, Cook and Kairiukstis 1990, chapter 3). In these situations, radial growth patterns have been successfully used to detect and quantify disturbance events (Lorimer and Frelich 1989, Payette et al. 1990, Nowacki and Abrams 1997, St. George and Nielsen 2000, Rentch et al. 2002).

4. Structural Evidence

- a. Canopy structure.
- b. Diameter distributions. See Heinselman (1973) for landscape-level reconstructions of disturbance events.

Additional information can be obtained through:

- 5. Historical Accounts.** Journals, chronicles, diaries, etc., from early explorers, surveyors, settlers, and early newspaper reports can be used to document pre- and post-European disturbance regimes (Day 1953). Historical maps (Van Wagner 1988, Payette et al. 1989).
- 6. Early Land Surveys.** Pre-European settlement disturbance regimes (disturbance types, sizes, intensities, frequencies) have been successfully chronicled by GLO Survey (Grimm 1984) or equivalent survey data (Seischab and Orwig 1991).

Disturbance regimes have been described for conifer-northern hardwoods (Lorimer 1977; Dunn et al. 1983; Canham and Loucks 1984; Whitney 1986, 1987), pine forests (Whitney 1986, 1987), swamp conifer forests (Whitney 1986, 1987), and boreal forests (Lorimer 1977). Early government land surveys can be used to estimate pre-European settlement fire frequency in pyrogenic landscapes (Lorimer 1980). The effects of Native American disturbance on pre-European forests have been traced through catchment analysis of witness-tree data (Black and Abrams 2001b).

Existing Vegetation

While *existing* vegetation information is also critical for sound forest planning, it serves a different purpose than TEUI. Whereas TEUI seeks to identify differences in the inherent potential of land units to generate ecosystem diversity and maintain its functions, existing vegetation maps reflect the current state of ecosystem structure and floristic composition. Potential and existing vegetation maps therefore provide different— but related and equally important— sets of information for forest planning. Protocols for classifying and mapping existing vegetation are described in the draft *Existing Vegetation Classification and Mapping Technical Guide* (Brohman et al. 2005).

Potential Natural Vegetation

PNV is *the vegetation that would become established if all successional sequences were completed without human interference under present climatic and edaphic conditions* [adapted from Tüxen (1956) as translated by Mueller-Dombois and Ellenberg (1974)].

Environmental conditions include climate, geology, geomorphology, and soil characteristics. Although it is important in classifying PNV to separate potential vegetation from these and other environmental variables, environment of course strongly influences development of PNV. “Present climatic and edaphic conditions” includes conditions created by past human activities (Tüxen 1956 as cited by Mueller-Dombois and Ellenberg 1974), such as soil loss. PNV may include naturalized, non-native species. Introduced species capable of displacing native species represent a change in floristic conditions that changes the PNV of a site. These new species may have been introduced by natural migration or by human actions.

Utility of Potential Natural Vegetation

Historically, the completion of the successional sequence (the sere) in the above definition was seen as progressing toward a stable, climax state limited only by climatic constraints. In recent years, this concept of climax as a single stable state has been shown to be overly

simplistic (Cook 1996). Following disturbance, vegetation on similar sites can proceed toward multiple possible future conditions. Our objective in classifying and using PNV, however, is not to promote the climax concept as a certain, rigid endpoint to succession. Rather, our goal is to capture the land's capability to support certain vegetative ecosystems by using potential vegetation as a concise, easily communicated and validated "shorthand" to describe this capability. PNV, then, is best thought of as the vegetation expressing its potential on the land, and can occur at all scales from site to region.

PNV should always be seen in the context of existing and historic vegetation. Our understanding of landscapes is likely to be incomplete without a full understanding of how existing, potential, and historic vegetation relate to each other. Existing and historic vegetation have been described previously in this document.

The objective of PNV classification is to concisely describe the capability of land to produce vegetation and support other ecosystem processes and functions through a well-defined vegetation description. Although this approach is only approximate, or may be overly simplified in some cases, this does not mean that PNV is not useful. Indeed, there may be value in this simplification, provided we are fully aware of its weaknesses, because information that is too detailed or complicated quickly loses currency with land managers. PNV is one of the most useful integrated expressions of environment we have that is related directly to vegetation. It has been widely and successfully used for planning at project, national forest, and river basin scales.

PNV is a more permanent feature of the landscape than is existing vegetation and sets the context in which a variety of structural and compositional stages of vegetation may occur. Consider an acre of PNV forest on deep soils adjacent to an acre of PNV grassland on shallow soils. Vegetation structure and composition of each acre can vary within the environmental constraints of each site. The PNV grassland acre of shallow soils is incapable of supporting a forest, but the PNV forest acre may support a variety of grassland, shrubland, and forested communities. The acre of PNV grassland will only support a limited variety of grass and forb communities. The PNV classification of the 2 acres would always be different, but they may at times support the same existing vegetation.

When PNV is coupled with other key landscape elements (soil, landform, climate, and geology) to identify an ecological type classification, PNV becomes more useful. For example, the geographically widespread subalpine fir/grouse whortleberry (ABLA/VASC) plant association occurs on a variety of sites. When soils and landform are used along with this plant association to classify ecological types, more precise descriptions of site potentials emerge.

In summary, PNV classification is a pragmatic shorthand means of understanding and communicating vegetative site differences. It is used along with landscape elements to classify ecological types. See 1.3.2 Ecological Classification for further details.

Potential Natural Vegetation Classification Criteria

The plant association is the fundamental unit of vegetation taxonomy for both potential and existing vegetation. Other levels of vegetation classification are derived from the association. The FGDC (1997) *Vegetation Classification Standard* specifies that the term “association refers to existing vegetation, not a potential vegetation type.” In other words, the term association does not necessarily refer to a climax plant community. This usage predominates in vegetation ecology (Krebs 1972, Mueller-Dombois and Ellenberg 1974, Barbour et al. 1980, Collinson 1988). In contrast, the USDA Forest Service (1991b) and USDA Natural Resources Conservation Service (NRCS) (1997) have used the term ‘plant association’ to refer to a climax or potential natural plant community, following Daubenmire (1968). The FGDC standard mandates that term ‘association’ or ‘plant association’ not be used to imply a climax plant community. However, it is acceptable to classify PNV at the association level of vegetation taxonomy.

Community composition is the “kinds, absolute amounts, or relative proportions of plant species present in a given area or stand” (Brohman and Bryant 2005). In practice, we recommend use of absolute areal percent cover as the best method to capture the amount of a species present. Areal percent cover is the fraction of a sample plot covered by the species of interest. This has the advantages of both simple data collection and good correlation to changes in site characteristics.

A vegetation classification in itself does not include abiotic factors. (The direct combination of a vegetation classification taxon and its abiotic counterparts defines an ecological type.) In developing a PNV classification, however, both plant abundance and environmental data are critical, since relating the amount of a species to site characteristics—soil moisture and nutrient status, aspect, elevation, etc.—defines the threshold separating one community from another. For example, 3-percent areal cover of shield fern is used in southeastern Alaskan western hemlock forests to characterize an ecosystem with well-aerated, nutrient-rich soils. Sites with less than 3-percent cover of shield fern have typically not reached this threshold of soil nutrient availability, and are classified as a different association. Such a classification would not be possible without correlating the vegetation data to soils data. This is a core principle of classifying potential vegetation: characterizing vegetation by changes in environmental thresholds rather than the simple abundance of each species. These changes reflect a species’ change in abundance along

environmental gradients (species amplitude). This is also why the modern concept of PNV centers on capturing the diagnostic structure, function, and composition of an ecosystem—its potential—rather than identifying a climax plant community state.

Diagnostic species are “any species, or group of species, whose relative constancy or abundance clearly differentiates one [vegetation] type from another” (Jennings et al. 2004). This definition implies that diagnostic species must be determined empirically through analysis of plot data (Mueller-Dombois and Ellenberg 1974). Identifying diagnostic species is an inherent part of classifying associations and alliances. Diagnostic species include dominant, differential, character, and indicator species. These are defined as follows:

Dominant species—“the species with the highest percentage of cover, usually in the uppermost ... layer” (Kimmins 1997 as cited in Jennings et al. 2004). Dominant species represent a quantitative difference in composition between vegetation types. Two stands or types may have identical floristics (plant species present) but differ in dominant species.

Differential species—“a plant species that, because of its greater fidelity in one kind of community than others, can be used to distinguish vegetation units” (Gabriel and Talbot 1984 as cited in Jennings et al. 2004). A differential species is usually present in one vegetation type but absent in other types. They constitute a floristic or qualitative distinction between vegetation types.

Character species—“a species that shows a distinct maximum concentration (quantitatively and by presence) in a well-definable vegetation type” (Mueller-Dombois and Ellenberg 1974). Character species constitute a quantitative difference in composition between vegetation types.

Indicator species—“a species whose presence, abundance, or vigor is considered to indicate certain environmental conditions” (Gabriel and Talbot 1984 as cited in Jennings et al. 2004). Indicator species may represent either a qualitative or quantitative distinction between community types.

Dominant species are generally self-evident. Other diagnostic species are typically determined empirically through analysis of species abundances and environmental data. Plots are grouped on or by species composition. This is often done with an algorithm to objectively search for groups of species that occur together repeatedly across the landscape. The diagnostic value of a species may change from one part of its geographic range to another because of genetic variation, compensating environmental factors, or changes in associated species.

Potential Natural Vegetation Hierarchy

PNV can be classified at four hierarchy levels: series, subseries, plant association, and plant association phase. The four taxonomic levels are defined as follows:

- A **series** is a taxonomic unit of PNV classification that aggregates plant associations that share the same climax species in the dominant layer. In forested vegetation this is typically the most shade tolerant tree species capable of occupying a site. The term series traditionally has been applied only to climax vegetation. Analogous terms for existing vegetation include *dominance type* and *alliance* (Jennings et al. 2004).
- A **subseries** is a taxonomic subdivision of a series that groups plant associations that share diagnostic species which show similar relationships to major environmental gradients (Mueller-Dombois and Ellenberg 1974). Regional terminology equivalent to the subseries concept may include *Plant Association Groups* and *Habitat Type Groups*, although in practice these groups sometimes contain members from different series. Analogous terms for existing vegetation include *alliance* and *suballiance*.
- A **plant association** (or association) is “a recurring plant community with a characteristic range in species composition, specific diagnostic species, and a defined range in habitat conditions and physiognomy or structure” (Jennings et al. 2004). Although the FGDC (1997) Vegetation Classification Standard specifies that the term “plant association” does not imply a climax plant community, it is acceptable to classify PNV at the association level of vegetation taxonomy. Plant associations are named after diagnostic tree, shrub, and herb species. *Habitat Type* serves as a loosely equivalent term to plant association in some regions.
- A **plant association phase** is a taxonomic subdivision of a plant association based on one or more diagnostic species. *Habitat Type Phase* serves as equivalent terminology to the plant association phase concept used by some regions.

The hierarchy is applied as illustrated in table 1.2, which shows examples of three levels in the PNV hierarchy. Any PNV identification within the hierarchy infers all PNV in levels above, but not the reverse. For example, the Big Sagebrush/Bluebunch Wheatgrass p.a. is a shrubland in the Big Sagebrush Series by definition. Conversely, the Big Sagebrush Series does not necessarily imply the Big Sagebrush/Bluebunch Wheatgrass p.a. as there are other plant associations within the Big Sagebrush Series. Coding for individual species is taken from the NRCS PLANTS database.

Table 1.2. *Potential natural vegetation hierarchy examples.**

Series	Subseries	Plant association	Plant association phase
White fir (ABCO)	Reserved	White fir—Douglas-fir/Rocky Mountain maple (ABCO-PSME/ACGL)	Creeping barberry phase (ABCO-PSME/ACGL, MARE11)
Quaking aspen (POTR5)	Reserved	Quaking aspen/Beaked hazelnut (POTR5/COCO6)	Western Brackenfern phase (POTR5/COCO6, PTAQ)
Twoneedle pinyon—Utah juniper (PIED-JUOS)	Reserved	Twoneedle pinyon—Utah juniper/Utah serviceberry—alderleaf mountain mahogany (PIED-JUOS/AMUT-CEMO2)	Greenleaf manzanita phase (PIED-JUOS/AMUT-CEMO2, ARPA6)
Sagebrush (ARTR2)	Reserved	Big Sagebrush/Idaho fescue (ARTR2/FEID)	Sticky purple geranium phase (ARTR2/FEID, GEVI2)
Tufted hairgrass (DECE)	Reserved	Tufted hairgrass—Slender wheatgrass (DECE-ELTR7)	N/A
Porter's wild lovage (LIPO)	Reserved	Porter's licorice-root—lodgepole lupine (LIPO-LUPA8)	N/A

*Examples are adapted from Johnston (1989). Symbols for species are from PLANTS (USDA NRCS 2004).

Types of Potential Natural Vegetation

Different combinations of macroclimate, topography, and soils can result in similar growing conditions and support the same PNV. However, the same PNV may reflect a different limiting factor in each case. Differences in limiting factor can result in different responses to vegetation management, even though the PNV is the same. It is, therefore, useful, to identify the environmental factors influencing vegetation development.

Based on Tansley's (1935) "polyclimax" theory, Daubenmire (1968) describes categories of climax vegetation based on which environmental factor most directly influences vegetation composition and structure. Similar categories are useful for describing the environmental factor most strongly influencing PNV on each ecological type. Although Daubenmire underestimated the role of natural disturbances (Cook 1996), the categories are useful for describing the effects of a given disturbance. The following discussion and terms are based on Daubenmire's (1968) treatment.

PNV types that reflect climatic, edaphic, and/or topographic conditions have been referred to as *primary PNV types*. PNV types that depend for their maintenance on periodic natural disturbance are called *secondary PNV types*. Primary PNV reflects the effects of inherent physical ecosystem attributes (or landscape elements) such as climate, geology, geomorphology, and soil properties. Secondary PNV is maintained by a specific type of ecosystem process (i.e., natural disturbances such as wildfire). By definition, vegetation maintained by periodic human activity is not PNV.

Categories of primary PNV include the following:

Climatic PNV—Any PNV type that reflects macroclimatic conditions and shows no dependency for its maintenance on periodic natural disturbance. Seasonal air temperatures, the amount and distribution of precipitation, and light intensity are the predominant elements of macroclimate.

Edaphic PNV—Any PNV type that differs significantly from the climatic PNV of an area due to soil properties not related to slope or topographic position. Examples of soil properties that may override the influence of macroclimate include depth, stoniness, texture, pH, and nutrient status. Many of these properties are affected by geologic parent material and geomorphic process.

Topographic PNV—Any PNV type that differs significantly from the climatic PNV of an area due to microclimatic conditions created by topographic characteristics. These can include steep slopes, north or south aspects, and areas of snow accumulation or loss.

Topo-edaphic PNV—Any PNV type that differs significantly from the climatic PNV of an area due to a combination of microclimatic and soil conditions created by topographic characteristics. An example is an aspen grove growing in a kettle where fine sediments accumulate, creating finer-textured soils. Drifting snow accumulates in the kettle, creating a wetter microclimate.

Categories of secondary PNV include the following:

Pyric PNV (or fire PNV)—Any PNV type that differs significantly from the primary PNV of an area due to periodic wildfire. A pyric PNV maintains its composition and structure only as a consequence of periodic natural burning, which eliminates fire-sensitive species and maintains fire-tolerant or fire-dependent species.

Zootic PNV—Any PNV type that differs significantly from the primary PNV of an area due to repeated native animal activity (such as grazing, trampling, burrowing, etc.) or periodic infestations of native insects or diseases.

A particular site may be described in terms of both a primary PNV and a secondary PNV type. For example, many areas in the Great Basin were dominated by big sagebrush with a 20- to 40-year fire return cycle prior to settlement. Since settlement, fire suppression has greatly lengthened the fire return interval, which has allowed juniper to dominate these areas. On such sites juniper is the climatic PNV and big sagebrush is the pyric PNV.

In another widespread example, cheatgrass has become the pyric PNV on many areas where big sagebrush is the climatic or edaphic PNV. The presence of highly flammable cheatgrass has shortened the fire return interval from 20 to 40 years to less than 10 years, which effectively prevents the reestablishment of sagebrush.

State and Transition Models

Understanding vegetation dynamics as influenced by soil, climate, topography, and time is essential for accurately classifying, mapping, and interpreting ecological types. As soil and plant community develop on a site, succession occurs. The state and transition model is one successional model that describes how different disturbances (fire, flooding, grazing, mechanical, air pollution, insects) and stresses (drought, increased precipitation, climate change and variability, exotic species) affect changes in the plant community. This model assists in developing successional pathways (transitions) and plant communities (states) that evolve under various climates and management practices. State and transition models are conceptual and based upon nonequilibrium ecology and depicted through box-and-arrow diagrams in which boxes represent observed or theoretical ecosystem states and arrows represent the observed or theoretical transitions among these states (figure 1.3). They are essentially a means of mapping system behavior in the absence of adequate predictive models (Westoby et al. 1989). Traditional theories of plant succession leading to a single climax community have been found to be inadequate

Figure 1.3. Broad application of the state and transition concepts. Derived from the Society for Range Management (SRM) Task Group on Unity in Concepts and Terminology (1995). The plane labeled SCT (site conservation threshold) represents a change from one ecological site to another and may also be considered a threshold between two states. The individual boxes or ovals represent plant communities or seral stages that exist within one state (Stringham et al. 2001).

for understanding the complex successional pathways of semiarid and arid ecosystems. Plant succession as influenced by arid and semiarid environments change at different temporal and spatial scales than communities growing within moister more humid and colder environments. These communities often exhibit nonlinear dynamics and are beyond the basic description using linear Clementsian climax theory.

A state is the general description of the known ecological type characteristics and properties. It is a recognizable, resistant, and resilient complex of two components: the soil base and the vegetation structure. The vegetation and soil components are necessarily connected through integrated ecological processes that interact to produce a sustained equilibrium, or stability, that is expressed by a specific suite of vegetative communities and is not simply reversible in the linear successional framework. Stability refers to the capability of the state to return to its original vegetative structure when stresses or disturbances are removed.

As the characteristics and properties or function significantly change there is a transition to a new state. A transition is a trajectory of the system change triggered by natural events, management actions, or both that will not come to rest until a new equilibrium is established. The processes that cause a shift from one state to another are called transition pathways. Transitions can be transient or persisting depending upon the frequency, magnitude, and extent of the disturbance. Regardless of the rate of change the system does not stabilize until the transition is complete.

Through inventory and analysis it is important to differentiate between processes that influence variation within states and those processes that result in crossing thresholds between states. Thresholds are boundaries in space and time between any and all states, or along irreversible transitions, such that one or more of the primary ecological processes has been irreversibly changed and must be actively restored before return to a previous state if possible (Stringham et al. 2001). This change is not reversible on a practical time scale without substantial inputs of energy. These processes need to be assessed and documented.

Characterization and Classification

The characterization and classification of plant communities for state and transition model development will follow standard sampling and description protocols as outlined in this guide. Document local agreement for development of this information in a memorandum of understanding (MOU) and/or work plans. The first vegetation state to describe using this model is the historic climax plant community. From this state, other states known to occur on the site and the transitions that lead to and from each state are devel-

oped. Vegetation composition, canopy cover, and structure are essential data elements for characterizing plant communities that can lead to classification of an ecological state. Documentation of these conditions is critical for establishing a framework for describing, understanding, and predicting ecosystem dynamics. Abiotic and flora characteristics and properties are fundamental in categorizing or classifying the ecological type as related to state and transition modeling.

Use in Mapping

Incorporating state and transition modeling into the TEUI mapping process requires considerable thought and planning to ensure scale and cartographic integrity are consistent with objectives of the inventory. Use the MOU and/or work plan to address the requirements of the TEUI mapping process. States of plant communities should be readily observable and documented. These states should be delineable at an appropriate scale and repeat to the extent that there is more than one area where the vegetative state can be located and observed. Similar vegetative states that are similar in composition, cover, and structure and separated by geographic features are mapped as the same repeating ecological type and ecological unit.

Application

Within the state and transition model, states can approximate seral stages or phases of vegetation development. Both narrow and broad interpretations of states can be made depending upon the establishment of thresholds.

Broadly applied, states are climate/soil/vegetation domains that encompass a large amount of variation in species composition. For example a grassland state would include many seral stages of the overall grassland community. These seral stages are within the amplitude of natural variability characteristic of the state and represent responses to a disturbance that do not force a breach of the threshold (Stringham et al. 2001). It is assumed that the domination of successional processes determines the boundary of the grassland state. In the broad definition of state, the range of natural variability characteristic of the plant communities within a site is the result of, and contributes to, the current functional integrity of the site's primary ecological processes.

The narrower interpretation of states allows for far less variation in plant community composition (figure 1.4). States are typically depicted as seral stages or vegetation development. A state change does not necessarily represent a movement across a threshold.

Figure 1.4. *Specific, or narrow, application of states with each state (box) representing one phase or seral stage of vegetation development. Transitions between states are indicated by arrows, and the dashed lines represents a threshold. The dashed transitional line signifies the requirement of substantial energy input to move the state back across the threshold (Stringham et al. 2001).*

The management and natural mechanisms responsible for community phase shifts and transition initiation must be included in the model description as applied in the TEUI process. The description of these mechanisms should contain information on their impact on primary ecological processes and the resulting change in the biotic community and system function. Typically, the change in the biotic community is documented, not the causal mechanism. Causes of vegetation change should be determined and the effects of this activity described. It is likely a combination of factors is responsible for these dramatic shifts.

1.4 Roles and Responsibilities

1.4.1 National Responsibilities

- Developing the TEUI program and implementing it as part of the agency's Inventory and Monitoring Framework.
- Developing classification and characterization standards for ecological types and ecological units and ensuring compatibility of any USDA Forest Service-generated descriptions across regional lines.

-
- Providing direction for the classification, inventory, and evaluation of ecosystem capability.
 - Ensuring consistency for national application and interpretation of ecological units.
 - Ensuring regions are completing the soils portion of TEUI to NCSS standards.
 - Ensuring regions are accountable for completion of TEUI to national standards and protocols and as scheduled in inventory and monitoring program plans.
 - Ensuring the incorporation of servicewide GIS data standards in the TEUI program.
 - Ensuring regions are collecting data that is compatible with corporate databases.

1.4.2 Regional Responsibilities

- Implementing the TEUI program to national standards and protocols.
- Developing TEUI information in advance of assessments, forest plan revisions, and monitoring as scheduled in the regions' inventory and monitoring program plan.
- Providing development of regional and local interpretations of ecosystem relationships, responses, diversity, productivity, and sustainability.
- Ensuring ecological type and map unit information is developed consistently across administrative units and major land resource areas. Coordinating with other agencies for correlation of ecological type descriptions and map units.
- Providing standards for application and interpretation of ecological types and map units, and ensuring consistency of standards and interpretations between regions and field units.
- Performing quality control so that performance measures and outcomes are accomplished for TEUI through instituting field review of TEUI products to assure consistency and quality.

1.4.3 Forest Responsibilities

- Implementing the TEUI program to national standards and protocols.
- Ensuring that TEUI is accomplished according to schedule.
- Collecting information to characterize ecological types and map units.

-
- Providing day-to-day quality control of mapping and data collection process.
 - Ensuring that ecological information is used in forest planning and assessments, and in project implementation on National Forest System lands.

1.5 Relationship to Other Federal Inventory and Monitoring Programs

1.5.1 Natural Resources Conservation Service

Soil Survey Program

The soil survey program of the United States is conducted under several statutory authorities. Public Law 89-560 directs the Secretary of Agriculture to (1) make an inventory of soil resources of the United States, (2) keep the inventory current, (3) make the information available in a useful form by preparing reports and interpretations, and (4) provide technical assistance and consulting services to promote the use and application of soils information. NRCS has lead responsibility for this effort (USDA NRCS 2003b).

The soil data collected through implementation of the *TEUI Technical Guide* will meet the following NCSS standards:

- Classification as found in *Keys to Soil Taxonomy* (USDA NRCS 2003a);
- Description, as found in *The Field Book for Describing and Sampling Soils* (Schoeneberger et al. 2002); and
- Documentation described in the *NSSH*, Part 627.08 (USDA NRCS 2003b) with exception of a TEUI map instead of a soil map.

The soil component of TEUs is verified in the field, and the soil correlation process in TEUI provides for consistent soil classification, naming, and interpretation. MOU and/or work plans serve as a cooperative agreement with NCSS partners and govern the management and administration of the soils portion of the TEUI and address how NCSS standards will be achieved.

National Soil Information System

The National Soil Information System (NASIS) is a corporate database that stores soil survey data. Many of the data elements and attributes for soils identified in this technical guide are identical with those in NASIS. Methods of sharing these data between agencies can be accomplished through data cross walks and migration routines.

Ecological Site Information System

The Ecological Site Information System (ESIS) is the NRCS repository for data associated with the collection of forest land and rangeland plot data (vegetation) and the development of ecological site descriptions (ESD). While the data elements collected for TEUI and NRCS ecological sites are similar, they differ in that the ESIS data are not integrated, collected, or mapped as part of the soil survey program. ESIS is organized into two applications and their associated databases described below.

Ecological Site Description

The ESD application provides the capability to produce automated ESDs from the data stored in its database. The ESD application is the official repository for all data associated with the development of forest land and rangeland ESDs by the NRCS.

Ecological Site Inventory

The Ecological Site Inventory application provides the capability to enter, edit, and retrieve range, forestry, and agro-forestry plot data.

1.6 Quality Control and Assurance

Quality control and assurance are addressed for each protocol in chapters 2 and 3.

1.7 Change Management

1.7.1 Update Schedule

The *TEUI Technical Guide* will be updated as needed or as directed by Washington Office staff with the concurrence of the national and regional TEUI program leaders.

1.7.2 Process

The updated *TEUI Technical Guide* will be released for a 3-month review period. Regional TEUI program leaders will compile and consolidate reviews from their respective regions and submit edits to the national TEUI program leaders for consideration.

Peer Review

The *TEUI Technical Guide* will be reviewed by all involved in TEUI, including soil scientists, geologists, and ecologists throughout Government agencies and universities. A current list of reviewers is available in appendix G.

Regional Supplements

Regions may supplement the information in this technical guide with methods or guidance required for meeting specific issues or needs of the region.

Chapter 2. Landtype Associations Protocol

2.1 Objective

The objective of this protocol is to provide consistent standards for the mapping and documentation of landtype associations (LTAs).

The development of standard ways of delineating, classifying, and describing LTAs across broad geographic regions will increase the reliability and interpretation of these units for broad-scale analysis. In lieu of standards, LTAs become less defensible scientifically because of lack of peer review, and less defensible legally because adjacent entities, such as national forests, will be inconsistent in addressing the same or similar resource management issues (DeMeo et al. 2002).

2.1.1 Business Requirements

LTA maps and descriptions are primarily used in the land management planning process as analysis units to organize broad areas by suitability, identify restoration priorities, and serve as a coarse filter for protecting biodiversity (Almendinger et al. 2000). Because LTAs describe both the abiotic and biotic elements of ecosystems, they provide an excellent analysis unit for determining forest-level effects. For example, the Rio Grande National Forest Plan Final Environmental Impact Statement and Supplemental Information Report projected changes in vegetation structure class by LTA over time for each alternative, enabling the analysis of effects from timber harvest. LTAs were also used to prioritize areas of fuel treatment, determine suitable areas for livestock grazing, and analyze cumulative effects (USDA Forest Service 2002).

Perhaps the most useful application of LTAs is as a stratification tool to quickly organize the planning landscape and rank areas by relative suitability or concern. This application was demonstrated for addressing habitat needs of a rare species in DeMeo (2002), resulting in considerable savings in field inventory costs.

LTAs proved useful addressing many other land management issues such as mapping natural disturbance regimes, managing wildlife populations, and developing integrated landscape models (Smith 2002).

LTAs also are used as the initial stratification for the premapping of the landtype (LT) level mapping described in chapter 3. Because the landscape elements for LTA maps are classified at broader levels, they are effective in organizing the LT survey area for further stratification.

Finally, because they are fairly broad landscape units (hundreds of thousands of acres), LTAs can be grouped by forest vegetation zone, geology, or other factors and easily communicated to the public and land managers.

2.1.2 Products

LTA mapping generates a Geographic Information System (GIS) map layer, designed for display at the 1:100,000 scale with supporting data and map unit descriptions. For an overview of a national forest or subregion, maps at 1:250,000 are also useful, but not as a substitute for the 1:100,000 product. The attribute data for LTAs are similar to those of the LT, but classification of the landscape elements are made at a broader level. Table 2.1 describes the recommended level of classification for each of the landscape elements. Required and recommended map unit attributes (for LTAs only) are listed in table 2.2.

Table 2.1. *Comparison of elements for ecological units at landscape and land-unit scales.*

Planning and analysis scale	Ecological unit levels	Geology	Geomorphology	Soil	Potential natural vegetation
Landscape	Landtype association (LTA)	Primary lithology or groups of secondary	Geomorphic process and subprocess types	Great group and subgroup	Series and subseries
Land unit	Landtype (LT)	Secondary lithology	Landforms, element landforms, and morphometry	Subgroups, families, and series	Subseries and plant associations
	Landtype phase (LTP)	Secondary lithology	Landforms, element landforms, and morphometry	Series and phases of series	Plant associations and plant association phases

2.2 Planning and Design

Plan LTA development in advance of forest plan revisions or other broad-scale assessments.

LTAs are developed using an integrated top-down/bottom-up approach. Top-down refers to subdividing subsections into LTAs using available resource maps, remote sensing, and expert knowledge. Resource maps may include geologic, soils, vegetation, and shaded relief. Bottom-up refers to aggregating LTs into LTAs based on common attributes and ecological interactions. Both methods are acceptable, and both should be used to verify the LTAs are scientifically sound. For example, if LTAs were delineated top-down, use bottom-up information from LTs to verify the larger scale units are coherent. Similarly, bottom-up aggregation of LTs must be rigorously checked to ensure the attributes are described at landscape scale, and are not simply a list of fine-scale unit attributes.

Table 2.2. *Required and recommended attributes (elements) to describe landtype association map units.*

Required	Example	Recommended	Example
Map unit code	M221Aa01	Local climate	See below ¹
Map unit long name	North Fork Mountain/River Knobs	Elevation range	1,000 ft to 2,500 ft above sea level
Bedrock geology: primary	Sedimentary	Geomorphology: landform	Anticline
Bedrock geology: secondary	Sandstone/shales	Disturbance regime(s)	See below ²
Bedrock geologic age	Ordovician (sandstone) Silurian (shales)	Aquatic systems and types	Few intermittent streams
Surficial geology: primary	Unconsolidated	Drainage density patterns	Low density, trellis pattern
Surficial geology: secondary	Colluvium/residuum	Geologic formation	Brallier, Pocono, others
Surficial geology: origin	Sandstone/shale		
Geomorphology: geomorphic process	Tectonic		
Geomorphology: geomorphic subprocess	Folding		
Soil	Lehew-Dekalb-Hazleton complex		
Potential natural vegetation	Mixed oaks vegetation zone		

¹Annual precipitation: 30 inches. Mean temperature April through September: 64.0° F. Mean temperature October through March: 38.6° F.

²Historic 10-year average fire return interval (frequent low-intensity). Largely removed with fire suppression over past 70 years. Gypsy moth current disturbance; hemlock wooly adelgid entering area.

Top-down maps should be field verified to check LTA composition. Transects across the landscape, organized in a stratified random design, may be most effective. LTAs assembled from LTs should be rigorously reviewed to ensure they reflect processes and composition at LTA scale, and that the interrelationships of the LTs are understood. Remember to stay true to the processes and composition at landscape scale. LTAs are not simply the aggregation of finer scale units. LTs may be grouped in different ways, but only cohesive LTAs are consistent with landscape scale and processes.

2.2.1 Map Unit Design

At landscape scale, LTA map units are broad, ranging from 1,000 to hundreds of thousands of acres. Ecological types apply as they do at LT scale. Map units can therefore be made up of components of ecological types. Bear in mind, however, that these types must be made up of taxonomic units appropriate for the scale. For example, the potential vegetation attribute of the ecological type at this scale should be described at series or subseries scale—not plant association scale. Because LTAs are landscape units, the map polygons will repeat less often (or not at all) when compared with LT scale.

2.2.2 Standards

- Mapping scale is 1:100,000. Use top-down, bottom-up identification team approach and map unit design criteria in National Hierarchy (Cleland et al. 1997).
- Map unit size ranges from 1,000 to hundreds of thousands of acres.
- Attribute standards are detailed in tables 2.1 and 2.2.
- LTA are correlated within subregions and peer reviewed.

Naming Landtype Associations

No national standards are set for naming LTAs. Geomorphology, however, is often the major driver in delineating an LTA; thus, broad landforms are typically used in the name.

2.2.3 Map Unit Legend

The LTA map unit legend consists of a map unit symbol and a map unit name. LTAs are designated using codes that incorporate the section and subsection of the LTA, as well as a two-digit numeric code for the LTA. For example, the M221Aa01 code denotes the Ridge and Valley section (M221A), Northern Ridge and Valley subsection (a), and North Fork Mountain LTA (01).

Using such mnemonic devices makes the codes more easily recognizable. One drawback is that concatenating information from different hierarchy levels can make analyzing the data more difficult—consider sorting the data by subsection, for example, when the subsection codes are embedded—but generally relatively few LTAs exist per national forest, so the problem is not burdensome.

Valid Values and Codes for Terrestrial Ecological Unit Inventory Elements

It is useful to develop a list of valid values and codes for each inventory area that reflects the range available for each of the landscape elements for that area. These lists are developed based on the best available information and knowledge of the inventory area. They are updated throughout the life of the inventory based on additional knowledge gained through the inventory process. Use appropriate levels of classification listed in table 2.1 as guidelines for each element.

2.2.4 Delineation Criteria for Landtype Association Map Units

Delineation of ecological map units is not always a straightforward process. The delineation process attempts to create meaningful ecological units and break these units where ecological changes occur on the landscape. Fortunately, dependency among landscape elements allows the mapper to delineate significant changes in unseen elements such as potential natural vegetation (PNV) and soils using proxy indicators such as existing vegetation, morphometry, surficial geology, local climate, and landforms. In any case, the interrelationships between these indicators must be thought out and defensible.

To consistently delineate ecologic map units, the criteria for delineations must be easily observable at the level of mapping. For instance, at the LTA level it would be unfeasible to use individual soil bodies and PNV as delineation criteria because these elements are not observable at that scale. Instead, more readily available landscape elements such as bedrock geology and vegetation cover types reflecting regional climate would be more appropriate.

LTAs are delineated primarily on the boundaries between broad geomorphic units. Use a combination of tools (bedrock and surficial geology maps, raised relief maps, remote sensing imagery) to discern boundaries between mountains, glacial features, or other geomorphology. A team with geologic, ecological, and soils expertise can quickly draft lines on U.S. Geological Survey (USGS) 1:100,000 topographic maps. Another option is to use the Terrestrial Ecological Unit Inventory (TEUI) Toolkit—a computer package of GIS and other analysis tools—to build the draft LTAs.

Following the initial draft, subsequent review teams from other national forests, other agencies, and academia can improve the maps and make them more consistent with the delineation factors. Avoid splitting out inclusions and small areas of special interest. These should only be delineated at LT or landtype phase (LTP) level.

Observable delineation criteria enable land managers and users of the TEUI to more readily recognize ecological units during land management activities. If the user is unable to distinguish where ecological units diverge, a misinterpretation of the landscape capabilities and management may occur.

Actual line placement criteria (or delineation criteria) are often along areas that show significant change within a single landscape element, such as the change in the slope gradient in a mountain base or footslope position. These delineation criteria will often change, as the landscapes they differentiate change.

The specific delineation criteria must be selected with the goal of creating consistently repeating map units that have distinct capability ratings or management interpretations.

2.3 Mapping Landtype Associations

The following procedures are guidelines that apply to mapping LTAs. Usually, LTA delineation is based on broad geology and/or geomorphology, with climatic, soils, and vegetation effects in a supporting role. For example, a mountain may be used to define the boundary of an LTA, but its highest elevations split out as another LTA because of a distinct change in temperatures and a related striking change in vegetation. A distinct band of different geology/soils would be another reason for splitting out a different LTA on the mountain.

Design criteria should include construction of ecological types in accordance with this document. Ecological types at the landscape scale will of course be broader in nature than at land unit-scale and associated landscape elements are classified at higher (broader) levels (see table 2.1 for recommended levels of classification).

2.3.1 LTA Mapping Process

1. Conduct preliminary field reconnaissance.
 - a. Use field visits and overflights of the area to gain a better understanding of the landscape and distribution of ecological types within the inventory area.
 - b. Use the TEUI Geospatial Toolkit (USDA Forest Service 2005) to review “virtual flybys,” shaded relief models, distribution of vegetation, landforms, aspect, slope, and elevation gradients to better understand the landscape.
2. Create preliminary polygons.
 - a. Use 1:100,000 aerial photography, topographic maps, digital elevation models, digital orthophoto quadrangles (DOQs), satellite imagery, and other resource maps as appropriate to delineate preliminary polygons. Employ an interdisciplinary team with geology, ecology, and soils expertise. At this stage, geologic input will probably be the most important.
 - b. Use the TEUI Geospatial Toolkit or similar technology to delineate preliminary map polygons. Use the DOQ image as a base while using multiple windows to compare delineations to other resource maps such as satellite imagery, shaded relief, and 3-D views with appropriate themes draped over the base (USDA Forest Service 2005).

-
- c. Base delineation on sound photo interpretive principles using all observable features, as well as the specific criteria and class limits defined in the classification and/or descriptive legends for each of the landscape elements.
 - d. Develop map-unit concepts by organizing and grouping LT map units with similar combinations of map-unit characteristics such as landforms, vegetation, geology, slope, and elevation ranges. Geomorphology is likely to be the primary driving factor in delineating LTA map units. Describe what makes a map unit different than those surrounding it or the map unit significance.
 - e. Use observable properties on aerial photography or other imagery when delineating map units.
 - f. Use caution when relying on visible existing vegetation from aerial photographs or as satellite imagery, as it may not represent PNV. Knowing the disturbance history will help locate areas where potential vegetation and existing vegetation may differ.
3. Develop preliminary map unit legend.
 - a. Develop a connotative legend using the procedures described in section 3.2.2, “Connotative Legends.”
 - b. Label polygons on photos, Mylars, and/or the coverage being created using the digitizing method in the TEUI Geospatial Toolkit.
 4. Review or develop new classifications as appropriate.
 - a. If PNV and geologic information are lacking in some areas, perform limited fieldwork to develop preliminary landscape element classifications and legends.
 - b. Use summaries of existing LT to develop ecological classifications or identify LT and their associated patterns using a field sampling process. See 2.3.1 Part 6.
 5. Incorporate existing information.
 - a. If existing LTs are available, aggregate these to form LTAs. This can be done with GIS, if available, or used to guide delineation of the LTA boundaries, if done by hand.
 - b. Use other maps such as geology maps, State Soil Geographic Database soil maps, vegetation maps, shaded-relief maps, and other mapped data to visualize and delineate LTAs.

-
6. Conduct field sampling.
 - a. If existing LTs are not available, verify LTA maps by sampling field data. A systematic sampling method employing transects across the landscape will be most efficient. A lower sample density than for corresponding land-unit mapping should be used for this step. For LTA verification purposes, intensive data are not critical. Transects to document changes in slope, landform, geology, soil subgroups, and vegetation series will typically be adequate.
 - b. Ensure data is adequate for correlation of LTA within subregions, and correlation of ET within LTA if a bottom-up process is used.
 7. Perform quality control.
 - a. Perform quality control checks on mapping, documentation, sampling procedures, and the accuracy and precision of estimates. Design the checks into the work plan development process, and perform them progressively during the mapping and classification process. Quality control checks range from scheduled field reviews to daily assists. The mapping team's primary responsibility is to ensure the application of quality control.
 - b. Ensure that LTA meet minimum documentation standards. Correlate LTA within subregions and patterns of LT within LTA.
 8. Enter Data.
 - a. Progressively enter data into the Natural Resource Information System (NRIS) Terra database. Additional regional tables may be needed to ensure more localized interpretations needs are satisfied.
 - b. Minimum data include GISDD requirements and those in table 2.2.
 9. Document map units.
 - a. Develop block diagrams depicting pattern or associate of map units concepts.
 - b. Collect photographs to catalog and document landscapes, vegetations, soils, and geology.
 - c. Provide statements of significance (i.e., those characteristics that distinguish the observed LTA from surrounding LTAs).

10. Finalize mapping and classifications.

- a. Finalize legend.
- b. Finalize mapping.
 - i. Match adjacent LTA mapping. The completed LTA maps should be joined to adjacent survey areas. A quality join must be maintained along the inventory boundary. Accomplishing a quality join requires that the map-unit delineations, attributes, and interpretations match across the boundary.
 - ii. Compile mapping to a stable base. Compilation methods will vary according to specific mapping techniques used on an inventory. Typically, lines are transferred and registered to a stable-based Mylar, and scanned or digitized into the GIS environment. Alternatively, if onscreen digitizing is used to develop, maintain, or adjust mapping products, this step may not be required.
 - iii. Scan or digitize mapping. All mapping layers should be prepared for scanning or digitizing according to national cartographic standards. It is also useful to code LTs with LTA identifiers so LTA maps can also displayed at 1:24,000 scale. This step will greatly facilitate analysis for planning purposes.
- c. Finalize any taxonomic classification developments including PNV and ecological type classifications.

11. Finalize descriptions for map units and ecological types.

- a. Distribute draft map and documentation for peer review. Peer review among national forests and partners within your region or subregion is particularly valuable.
- b. Map unit descriptions must meet standards outlined in table 2.1 and table 2.2, GIDD standards, and contain a statement of significance.

12. Develop interpretations.

- a. Develop interpretations for the map unit component and/or landtype association.
- b. Management implications are an important part of this work, and indeed, are the end objective of all ecological unit mapping. Implications are tailored to the needs of the local area, and can include the following information:

-
- Relative value of biodiversity, as measured by plant or animal species richness, diversity of plant community and patch types (beta diversity), etc.
 - Suitability for silvicultural prescriptions, reforestation, methods, etc.
 - Prescribed and wildfire implications.
 - Habitat for species of management interest.
 - Ecosystem productivity, both terrestrial and aquatic.
 - Historic range of variation, and what the LTA will likely look like in the future without treatment.
 - Susceptibility to acid rain, ozone, etc.
 - Susceptibility to insects and diseases.
 - Soil erosion and compaction.
 - Mass wasting and other geologic hazards.

13. Prepare manuscript.

Written documentation for LTAs should be organized by national forest, subregion (group of forests), or by region. Document should include objectives, definition of an LTA and explanation of the hierarchy of ecological units, methods used to delineate and attribute LTAs, description for each LTA using table 2.1 as a guide, management implications, and literature cited. See 11.b. for additional instruction on map unit descriptions.

2.3.2 Logistics

Facility and Equipment Needs

Base Maps

USGS topographic maps at 1:100,000 scale are considered the desired publication scale map for LTAs. This map is usually used for forestwide planning efforts.

Aerial Photography

Aerial photography may be used as a base map as well as for field reference. For LTAs, using photography at scales ranging from 1:60,000 to 1:100,000 is generally recommended.

Common types of aerial photography include natural color, infrared, and large format. Using stereo pairs to view landscapes in three dimensions can aid in interpreting landscape elements.

The Aerial Photography Field Office (APFO), Farm Service Agency, is the primary source of aerial imagery for the U.S. Department of Agriculture. More than 10 million images are stored in the APFO library, dating from 1955 through the present. For more information, visit <http://www.apfo.usda.gov>.

The National High Altitude Photography program, initiated in 1980, was coordinated by the USGS to acquire aerial photography of the 48 conterminous States every 5 years. Visit <http://edc.usgs.gov/Webglis/glisbin/guide.pl/glis/hyper/guide/napp>.

Digital Orthophoto Quadrangles

A DOQ is a digital representation of an aerial photograph with ground features located in their true positions. Displacements in imagery caused by camera tilt, sensor orientation, and terrain relief are removed. DOQs combine the image characteristics of a photograph with the accuracy and scale associated with a map. Though they cannot be used for stereo interpretation, they are an excellent digital base map for onscreen digitizing or review of registration. For more information about DOQs, visit <http://fsweb.gsc.wo.fs.fed.us/>.

Digital Elevation Models

A digital elevation model is a digital data file containing an array of elevation information over a portion of the Earth's surface. This array is developed using information extracted from digitized elevation contours from primary base series maps. For more information, visit <http://fsweb.gsc.wo.fs.fed.us/>.

Satellite Imagery

The USGS National Center for Earth Resources Observation and Science at <http://edcwww.cr.usgs.gov/> provides a variety of satellite imagery.

The Remote Sensing Application Center (RSAC) at <http://fsweb.rsac.fs.fed.us/> is a detached Washington Office Engineering Staff unit located in Salt Lake City, UT. The mission of RSAC is to provide technical support to U.S. Department of Agriculture (USDA) Forest Service resource specialists and managers in the use of remote sensing, image processing, GIS, and related geospatial technologies for all resource applications. RSAC is collocated with the USDA Forest Service Geospatial Service and Technology Center and the USDA APFO.

Hardware and Software Requirements

Field offices should have the most recent corporate hardware and software upgrades, including requirements for NRIS Terra and the TEUI Geospatial Toolkit.

Field Equipment

Appendix H provides a complete list of equipment and sources.

2.3.3 Personnel Requirements

TEUI Team Expertise and Makeup

The LTA development core team should consist of personnel with expertise in geology, soils, and ecology. The core team should be kept small, with no more than three or four personnel. Other personnel have an important role in reviewing and refining the products. Typically, ad hoc USDA Forest Service review teams, as well as interagency and academic reviewers, are involved.

Training and Qualifications

Competent geologists, soil scientists, and ecologists should already have the basic skills to build LTA map units and descriptions. Training in the TEUI Geospatial Toolkit is certainly called for. The core team should make themselves fully familiar with existing relevant literature, data, and maps.

Job Descriptions

Examples of job descriptions are available in appendix I.

2.4 Data Collection

LTA data collection is much less intensive than for development of LTs or LTPs. LTAs can be described by a panel of experts, drawing on existing maps, imagery, publications, experience, and appropriate landscape data or existing LT data can be summarized or reclassified for use at the landscape scale.

Data collection can also be used to predict or identify LTs and their occurrence within potential LTA. Landscape transects are commonly used for this purpose.

2.5 Data Storage

LTA data will typically take the form of attribute tables (such as table 2.2), GIS coverages, and written documentation. Quantitative data are typically summarized from finer scale field data. All LTA data will be stored in the NRIS Terra database. See 2.3.11 part 11b. for additional instructions.

2.6 Analysis

Analysis takes the form of expert teams working with existing maps, data, and publications. Rigorous classification of vegetation or soils usually takes place at finer (LT) scale, and then taxonomic units are aggregated (appropriately) to form units appropriate for LTA scale. For example, for potential vegetation, plant associations can be classified from field plot data, and then these taxa are aggregated and reclassified into new taxa appropriate for use at LTA scale.

2.7 Reporting

See section 2.31, item 13 above. Documentation should at a minimum have rigorous peer review, and ideally be published as a research station general technical report.

Chapter 3. Landtype Protocol

3.1 Objective

The objective of this protocol is to identify the standards and guidelines for developing terrestrial ecological units (TEUs) at the landtype (LT) level of the National Hierarchy. TEUs are areas of relatively stable environments that depict the inherent properties of their ecosystem elements. TEUs are not static, however, and may be refined and updated as knowledge about the ecosystems they capture is accrued. When used in conjunction with information on existing conditions, historical conditions, and ecological processes, TEUs provide a foundation for making sustainable land management decisions.

Ecological units represent consistently repeating portions of landscapes with similar combinations of ecological types. These ecological types represent the distinguishing characteristics of a particular geographic area. Ecological units identify interrelationships among ecological types and establish a tie between observed ecological condition and predicted environmental response. Table 1.1 provides a summary of the Terrestrial Ecological Unit Inventory (TEUI) elements. Detailed descriptions of each element are provided in chapter 1.

3.1.1 Business Requirements

LT and landtype phase (LTP) maps are used for comprehensive forest plan revisions, watershed assessments, burned area emergency rehabilitation efforts, wildlife habitat analysis, and project level implementation and analysis. Interpretations developed from the data are valuable for depicting land capability and potentials.

3.1.2 Products

The LT product is a Geographic Information System (GIS) map layer, developed at a 1:24,000 map scale, which meets all U.S. Department of Agriculture (USDA) Forest Service guidelines for TEUs and is registered to the primary base series maps. TEUI core attribute data are available in the corporate Natural Resource Information System (NRIS) Terra database, and map unit descriptions and ecological type descriptions are documented to the standards described in this technical guide.

3.2 Planning and Design

3.2.1 Ecological Type Classification and Characterization

An ecological type is a category of land with a unique combination of landscape elements. The elements making up an ecological type are climate, geology, geomorphology, soils,

and potential natural community. Ecological types differ from other ecological types in the ability to produce vegetation and respond to management and natural disturbances. Classification of ecological types is used to validate landscape stratifications, assist in map unit design and delineation, and describe map unit components.

Classification of Ecological Types

The classification process organizes and describes relationships between the inherent landscape elements. Preliminary or established ecological types are used to design and assist in the delineation of ecological units. Table 3.1 shows the suggested levels of detail for each element.

Table 3.1. *Suggested level of detail used for classification and mapping at the landscape and land-unit scales.*

Planning and analysis scale	Ecological unit levels	Geology	Geomorphology	Soil	Potential natural vegetation
Landscape	Landtype association (LTA)	Primary lithology or groups of secondary	Geomorphic process and subprocess types	Great group and subgroup	Series and subseries
Land unit	Landtype (LT)	Secondary lithology	Landforms, element landforms, and morphometry	Subgroups, families, and series	Subseries and plant associations
	Landtype phase (LTP)	Secondary lithology	Landforms, element landforms, and morphometry	Series and phases of series	Plant associations and plant association phases

Differentiation Between Ecological Types

At the landtype association (LTA) level, ecological types are driven by geomorphology, but strongly influenced by bedrock geology, parent material, soil subgroups, vegetation series, and climatic effects induced by elevation, growing degree days, or precipitation. Synthesis of data will rely more on existing information and expert panels than at the land-unit scale.

At the LT and LTP levels, ecological types are classified based on differences in potential natural vegetation (PNV), soils, local climate or microclimate, geomorphology, surficial geology, bedrock geology, and/or hydrology. Ecological type classification requires analysis and description of relationships among these elements. This work requires simultaneous analysis of these elements based on integrated plots, transect observation sites, and bedrock geology data.

Statistical analysis is appropriate where sampling is conducted in a random or systematic manner and a large enough sample of the population is present to capture the variability

in the landscape elements. Pattern analysis is suitable for all sampling designs. Pattern analysis methods include gradient analysis, ordination, and classification. Gradient analysis is used to determine the distribution of plant species and soil properties along easily recognized environmental gradients such as elevation and topographic moisture status. Ordination methods are used to detect less obvious relationships among landscape elements.

Naming Ecological Types

Ecological types are named using a minimum of a two-part soil and plant community name. Use soil series name, family name, or classes of soil taxonomy with or without accompanying terms to name the soil portion. Incorporate geologic, geomorphic, and/or landform names, if changes in them constitute differentia among the ecological types. Use the level of soil taxonomy (series, family, or higher category) that is needed to meet the objectives of the survey. Name the plant community portion according to potential natural community (USDA NRCS 2003). Some examples of names are displayed in table 3.2.

Table 3.2. *Examples of ecological type names.*

Code	Short Name (optional)	Long Name (required)
ET022	ABLA/VASC, Guiser family	Subalpine fir/grouse whortleberry, Guiser family
554.1		Lithic Haplustalfs, shallow LSM Pisos/ Loamy-skeletal, very cobbly 5 Quar mixed, mesic, sandy loam 0 ----
ET3001	Prime Giant Sequoia	Giant Sequoia, Holland soils, Granitic, gently sloped, fluvial process dominated
5	Dry Pine	Pinus/Vaccinium, excessively drained sands

Classes of soil taxonomy with or without accompanying phase terms are used to name the soil portion. Incorporation of geologic, geomorphic, and/or landform names is generally encouraged. Use the categorical level of soil taxonomy (series, family, or higher category) that is intended to meet the objectives of the survey. The vegetation portion is also named at the appropriate level for the objectives of the survey and level of documentation. Examples of map unit codes and names are shown in table 3.4.

Ecological Map Unit Design Criteria

Ecological map units are designed to represent the naturally repeating patterns of ecological types across the landscape. The map unit organizes these patterns and describes the interrelationships between the components that occur together in a continuum across the landscape. Be aware that map unit concepts often grade into one another and are not always distinct.

Map Unit Composition

Map units are typically composed of one or more ecological types or components. Ecological types are the taxonomic unit for which the map unit component is named. Ecological types may occur in one or more map units and their properties are derived from wherever that type occurs. The map unit component may also represent a narrower range of characteristics or properties of an ecological type because they are based on that part of the ecological type that occurs spatially within a specific map unit.

Map Unit Kind

TEUI incorporates the concept of “map unit kind” from traditional soil survey methods to help describe the relationships between map unit components. Map units are divided into four categories: (1) consociations, (2) complexes, (3) associations, and (4) undifferentiated groups (USDA NRCS 2003).

Consociations are map units in which one named component is predominant. These units are typical of uniform areas where one ecological type is dominant and can be delineated separately at the LT and LTP level of mapping.

Complexes and associations are map units in which two or more major components occur in regularly repeating patterns. In a complex, the major components cannot be separated at the scale of mapping. In an association, the major components can be separated (USDA NRCS 2003b).

Undifferentiated groups are used when the components are not consistently associated geographically and, therefore, do not always occur together in the same map delineation. These components are included in the same named map unit because their use and management are the same or very similar for common uses.

Major and Minor Components

Map units are composed of one or more major and minor components. Major components typically comprise 15 percent or more of the map unit. Minor components (inclusions) typically comprise less than 15 percent of the map unit. A minor component in one map unit may be a major component in another. Both major and minor components are used to develop the range in characteristics for the ecological type for which a component is named.

3.2.2 Standards

Mapping Standards

- Mapping scale for LTs is 1:24,000 and LTPs at 1:12,000. Use top-down, bottom-up interdisciplinary team approach (Cleland et al. 1997).

- Recommended minimum size delineations are 2 acres for LTPs and 6 acres for LTs.
- Minimum width is 2 mm or 160 feet on the ground at a 1:24,000 mapping scale.
- Linear features such as riparian or wetland areas less than 2 mm wide or less than 6 acres that encompass a stream may be mapped at the 1:24,000 scale as a TEU line segment or mapped as point features and indicated with the appropriate spot symbol.
- LT and LTP are correlated within LTA.

Documentation Standards

Document reliability of map unit characteristics through a systematic data collection process using transects, traverses, and observations. Determine documentation needs based on sampling intensity, level of taxonomic classification, standards requirements, and ecological type variability. Table 3.3 describes minimum levels of documentation. Design of the map units should be consistent with order of sampling intensity as described in the work plan. Table 3.5 describes sampling intensity levels.

Refer to NSSH Part 627.08 for documentation standards for soils in order to meet NCSS statements. A soil map is not required. However, a TEUI map is required in place of a soil map.

Table 3.3. *Minimum levels of documentation for landtypes.*

Landtypes		
Ecological type	Components	Map units
A minimum of three complete integrated plots that represent the concept of the ecological type in the survey area are recorded before an ecological type is added to the descriptive legend. Completed documentation must reflect the geographic and environmental range across which the ecological type is mapped. Representative sites for each ecological type are identified.	A minimum of three complete integrated plots that represent the concept of the component in the map unit are needed. Completed documentation must reflect the geographic and environmental range of the map unit. Integrated plots may be used from transects or traverses within the named map units.	A minimum of three transects with a minimum of 30 sample sites (integrated plots and/or observations) across geographic and environmental range of each map unit are recorded. Completed documentation must reflect the geographic and environmental range of the map unit. Each map unit component must have a complete ecological type description.

Naming Ecological Units

Name ecological units for one or more ecological types or for something that distinguishes and provides a brief description of that unit. Numbers or other brief descriptors may be used for complex units that prove difficult to name. Map unit descriptions must include the full technical names for each element used to characterize the ecological unit. Table 3.4 gives examples of ecological unit names.

Table 3.4. *Examples of ecological unit names for landtypes.*

Map symbol	Map unit name
2641	ABLA-PIEN/VASC, Ivywild Family—ABLA/VASC, Hensen Family—complex, 10–30-percent slopes
554	Lithic Haplustalfs, LSM, 5, 0, loamy-skeletal, mixed, mesic, shallow, very cobbly sandy loam, Pisos/Quar— Lithic Eutroboralfs, LSC, 5, 0, loamy-skeletal, mixed, shallow, very cobbly sandy loam, Pisos/Quga association: 15- to 40-percent slopes
3001	Giant Sequoia, Holland soils, Granitic, gently sloped, fluvial process dominated
5	Fire-dependent, multiple-aged, somewhat brushy, jack/red pine forests of somewhat excessively or well drained sandy/gravelly soils, flat to strongly rolling habitats
30SH123	PIPO/QUGA-Burnac—FETH-Acree complex on lower montane shale hills, 15- to 30-percent slopes
3622	Sedimentary Sideslopes, Big Sagebrush—Tall Forb Complex

Table 3.5. *Sampling intensity levels.*

Level of national hierarchy	Sampling intensity	Field procedures	Kinds of map units	Scales for field mapping
Landtype Phase	Sampling intensity 1—Intensive (i.e., watershed and landscape analysis, burned area rehabilitation analysis, forest and grassland project planning, species habitat modeling).	Collect data and document (integrated plots and/or observation sample sites) 90 percent of polygons for each map unit.	Consociations	1:12,000
Landtype	Sampling intensity 2—Intensive (i.e., watershed and landscape analysis, burned area rehabilitation analysis, forest and some broad scale project planning).	Collect data and document (integrated plots and/or observation sample sites) 75 percent of polygons for each map unit.	Mostly consociations and some complexes	1:24,000
Landtype	Sampling intensity 3—Extensive (i.e., forest planning and broad scale assessment, watershed and landscape assessment).	Collect data and document (integrated plots and/or observation sample sites) 50 percent of polygons for each map unit. LTs are delineated by observation and interpretation of remotely sensed data.	Mostly associations or complexes, and some consociations	1:24,000

Table 3.5. *Sampling intensity levels (continued).*

Level of national hierarchy	Sampling intensity	Field procedures	Kinds of map units	Scales for field mapping
Landtype	Sampling intensity 4—Extensive (i.e., general ecological type information for broad statements concerning land-use potential and general land management).	Collect data and document (integrated plots and/or observation sample sites) 25 percent of polygons for each map unit. LTs are delineated by interpretation of remotely sensed data.	Mostly associations; some complexes and consociations	1:24,000
Landtype association	Use existing information and expert panel.	Verify through existing landtypes or transects with intensity similar to sampling intensity 4 above.	Varies but must be at landscape scale	1:100,000

TEU Map Unit Legend

The TEU map unit legend consists of a map unit symbol and a map unit name.

Connotative Legends

Connotative legends may be used to display differentiating information in the map unit symbol. Connotative legends may be used at any level in the National Hierarchy. In this example of a connotative legend, the map unit symbol is connotative of climate zones and lithology in the survey's ecological section. For this survey area, eight distinct climate zones are defined by soil moisture and temperature; broad vegetation type (e.g., pinyon juniper, ponderosa pine, mixed conifer, spruce fir, and alpine); and associated environmental conditions such as precipitation, snowfall, and elevation. Lithology is denoted using either the primary or secondary lithology classes. Figure 3.1 provides an example of a connotative legend.

Figure 3.1. *Example of connotative legend.*

The map unit code is the final code applied to a TEU map unit. It is the key field between the database and the TEU GIS map coverage, provides a shorthand reference for map units, and can be used as a tool to query particular information about map units. It also allows the mapper easy recognition and recall of map unit concepts. The map unit code is used in the mapping process to designate polygons on aerial photographs or

quad sheets. Other landscape elements may be substituted in the above example as appropriate.

The TEU map unit code should be connotative (where possible), simple, and meaningful for grouping and sorting TEUs by the main differentiating criteria for the survey area. Following these objectives has proved useful for developing LTAs.

Lists of Valid Values and Codes for TEUI Elements

It is useful to develop a list of valid values and codes for each inventory area, reflecting the range available for each of the TEUI elements for that area. These lists are developed based on the best available information and knowledge of the inventory area. Update them throughout the life of the inventory based on additional knowledge gained through the inventory process. All lists use national definitions and codes. Use appropriate levels of classification listed in table 2.1 as guidelines for each element.

Description of TEUI Map Units

The TEUI map unit description is a summary of information about a map unit throughout its area of occurrence. A map unit description contains information about the composition, distribution, and extent of ecological types as well as the relationships between components. Additional map unit descriptors such as elevation, aspect, slope, mean annual precipitation, frost-free days, and average annual snowfall are also included.

The data necessary to develop a map unit description are generated from information gathered in the field (see appendixes C, D, and E), information gathered electronically (e.g., range in elevation for a map unit using a digital elevation model [DEM]), and information from existing data sources such as soil surveys. Examples of ecological map unit descriptions can be found in appendix F.

Mapping Ecological Units

Mapping begins after the development of preliminary map unit concepts. The landscape is stratified into map units according to established ecological type criteria. The objective is to minimize and characterize the variability within an ecological unit while placing the boundaries where significant changes occur within one or more elements.

Delineation Criteria

Delineation of ecological map units is not always a straightforward process. The delineation process attempts to create meaningful ecological units, and break these units where changes occur on the landscape. Fortunately, dependency among landscape elements

allows the mapper to delineate significant changes in unseen elements such as PNV and soils through proxy indicators such as morphometry, surficial geology, local climate, and landforms.

To consistently delineate ecologic map units, the criteria for delineations must be easily observable at the scale of mapping. For instance, at the LTA scale (1:100,000) it would be unfeasible to use individual soil bodies and PNV as delineation criteria because these elements are not observable at that scale. Instead, more readily available landscape elements such as bedrock geology and vegetation cover types reflecting regional climate would be more appropriate.

Unless all areas of a TEUI are to be field checked, the use of unseen elements such as soils and PNV as delineation criteria will introduce error into the mapping process. Even at sampling intensity 1, in which 90 percent of the polygons are visited, errors will be introduced if these criteria are used to delineate polygons. Instead, the use of readily observable features such as landform, slope morphometry, and local climate would be more appropriate.

The use of observable delineation criteria allows land managers and users of TEUI to more readily recognize ecological units during land management activities. If the user is unable to distinguish where ecological units diverge, then a misinterpretation of the landscape capabilities and management may occur.

Actual line placement criteria (or delineation criteria) are often along areas that show significant change within a single landscape element, such as the change in the slope gradient in a mountain base or footslope position. These delineation criteria will often change as the landscape that they are differentiating changes.

For example, while delineating a polygon of pure quaking aspen, the boundary may be delineated along the vegetative cover change (aspen to sagebrush) segments, along landform positions (backslope to footslope) for other segments, or along aspect changes in yet other segments.

The specific delineation criteria must be selected with the goal of creating consistently repeating map units with one or more components that have distinct capability ratings or management interpretations.

TEUI Attributes Linked to Aquatic Ecological Unit Line Segments, Valley Segments, or Polygons

Map units and components may be linked to a buffered stream line segment or polygon rather than a TEU polygon. This method may be desirable in describing riparian areas that are significant, but either too narrow (i.e., less than 2 mm) or too small (i.e., less than 6 acres) to map as a TEU. In this case, TEU attributes are assigned to the line segment or polygon (in the case of water bodies) associated with the riparian area being described. This attribution of line segments should be coordinated with the existing aquatic inventory if applicable. For example, a small riparian area along a valley segment may coincide with an aquatic ecological unit inventory line segment. In this case, a quality join should be completed with the aquatic inventory, or map units shared between the inventories.

Mapping Landtypes and Landtype Phases

The following procedures are guidelines that apply to mapping the LT or LTP regardless of whether development of the LT or LTP involves new polygon delineation or modification of existing soil survey polygons. The mapping process is more involved than for LTAs and generally takes 2 to 5 years to complete depending on the size, complexity, mapping intensity, and management objectives of the inventory area.

LT and LTP Mapping Process

1. Conduct preliminary field reconnaissance.
 - a. Take field trips and/or overflights of the area to gain a better understanding of the landscape and distribution of ecological types within the survey area.
 - b. Use the TEUI Geospatial Toolkit (USDA Forest Service 2005) to review “virtual flybys,” shaded relief models, distribution of vegetation, landforms, aspect, slope, and elevation gradients to better understand the landscape.
2. Create preliminary polygons.
 - a. Use existing or newly created LTA mapping as a starting point.
 - b. Use stereo pairs of 1:24,000 aerial photography, topographic maps, DEMs, digital orthophoto quadrangles (DOQs), satellite imagery, and other resource maps as appropriate to assist in delineating preliminary polygons.
 - c. Use the TEUI Geospatial Toolkit (USDA Forest Service 2005) to further help define and delineate preliminary map polygons. Use the DOQ image as a base

while using multiple windows to compare delineations as they appear on other resource maps such as satellite imagery, shaded relief, and 3-D-thematic views.

- d. Base delineation on photo interpretive principles using all observable features, and specific criteria and class limits defined in the classification and/or descriptive legends for each of the LT elements.
 - e. Develop a map unit concepts by organizing and grouping polygons with similar combinations of map unit characteristics such as landforms, vegetation, geology, slope, and elevation ranges.
 - f. Use delineation criteria to capture the location of spatial changes in the LT elements, such as landforms, vegetation, geologic structures, and weak and resistant materials whose properties are most observable on aerial photographs.
 - g. Clearly indicate which information is speculative and which is evaluated or derived from premap tools (e.g., slope, elevation, aspect).
 - h. Use caution when relying on visible existing vegetation from aerial photographs or satellite imagery, as it may not represent PNV. Knowing the disturbance history of an area will help locate possible areas where PNV and existing vegetation differ.
3. Develop preliminary map unit legend.
- a. Develop a connotative legend using combinations of the valid values and codes. Indicate if the map unit is provisional, additional, or accepted (USDA NRCS 2003).
 - b. Label polygons on photos, Mylars, and/or in the coverage being created using appropriate digitizing methods.
4. Review or develop new classifications as appropriate.
- a. Ensure soil classification is up-to-date (USDA NRCS 2003b). In some areas, a lack of PNV and geologic information may require limited fieldwork to develop preliminary classifications and legends.
5. Incorporate existing soil survey polygons.
- a. Develop a thorough understanding of the existing information to make decisions regarding the modification of polygon delineations. The purpose should be to retain the design of the existing map units where they meet all LT criteria. In this case, a simple crosswalk from the old map unit code to the new may suffice.

-
- b. Because not all existing soil survey map units meet TEUI criteria, understand the difference between modifications that affect the intent of the original map unit design, and those that do not. Many modifications to polygon delineations will not change the intent or design of the original soil survey map units. These modifications will not require additional documentation.
 - c. If necessary, include some modifications that change the central concepts of the original soil survey map units. In this case, additional documentation and field inventory will be necessary to meet NCSS requirements for soils. See 1.5 Soil Survey Program.
 - d. Apply the same standards for mapping the LT regardless of whether new or existing polygon delineation is considered. A number of variables are involved with using existing information, making it difficult to describe an exact process for developing the LT legend. Some of these variables include quality and availability of base maps, availability of aerial photos with original delineation, quality of original delineation, quality and availability of supporting documentation, and personal knowledge of the development of existing information.
 6. Incorporate water bodies.
 - a. Do not delineate water bodies and streams that appear as double lines on the primary base series maps as polygons during LT mapping. These features are incorporated from the core water layer during the map compilation process. Where a water body is completely enclosed by a LT polygon, the water body can be ignored during TEU mapping. Delineate any polygons adjacent to a water body by extending the polygon boundaries to an imaginary intersection in the center of the water body. This boundary will be a temporary misrepresentation of the TEU on the hard copy of the TEU map. The electronic overlaying process will place water boundaries from the water layer onto the TEU map. Water bodies may be delineated on the TEU map with a nonscanable color, if desired. Typically, the water bodies may be imported from cartographic feature files or DOQs.
 7. Conduct field sampling.
 - a. Select a sampling design commensurate with the inventory objectives and standards requirements. Consider the location of the plots on the landscape. In terms of efficiency, a stratified sampling design is best. Other considerations, however, such as time and cost, must be evaluated. Several sampling methods are summarized below. These may include one or a combination of the following methods:

-
- i. *Representative sampling.* Select representative premap polygons and sample typical locations for modal components. Traversing, a method of collecting representative samples, can verify the occurrence of ecological types within map units, develop additional ecological types, and meet documentation standards. Integrated plots should be located in areas of uniform vegetation and environment (i.e., landform, slope characteristics, soils, surficial geology). This technique is not statistically valid, but is suitable for pattern analysis.

Note: This method is biased toward the mapper's professional interpretation of what components to sample. It requires experience and local knowledge of what is being mapped. Sites are selected to capture the modal or dominant properties of each ecological unit component. This method is often the most time-effective and cost-efficient sampling design for ecological units.

- ii. *Random sampling.* Use random-number table or other method to obtain Universal Transverse Mercator coordinates. Establish rule base for handling access problems, disturbance areas, and other situations requiring design alterations.

Note: In practice this method will not be used often because of its inefficiency and high cost in time and funding. A random sample could result in samples clustered in one area, particularly if the sample size is low. One drawback of random sampling is the possibility that the sample will not represent the population (Barber 1988).

- iii. *Systematic sampling.* Select appropriate grid for size and variability of premapped polygons. Establish rule base for handling access problems, disturbance areas, and other situations that require design alterations.

Note: This method has the strength of avoiding bias but may have logistical weaknesses (possibly many plots in remote areas) or be biased by the spatial distribution of the landscape where regularly repeating patterns are not adequately sampled. To eliminate bias, check for randomness in the sampling frame (Barber 1988).

- iv. *Transect sampling.* Generate transect methods to minimize mapping bias. Establish rule base for handling access problems, disturbance areas, and other situations that alter transect layout. Located randomly within each stratification unit, transects should be oriented to capture the maximum variation in key environmental gradients, usually elevation, soil climate,

climate, soil taxa, or site productivity. Transect observation sample sites may include notes and partial descriptions, but must be done consistently.

Note: Transects offer several benefits. They can be used efficiently to incorporate both observation sample sites and intensive plots, thus accomplishing mapping, inventory, and classification objectives in a single field effort. They can be oriented to capture the maximum variation in environmental gradients (usually elevation, but others such as soil drainage or moisture are possible). They are an efficient way to deploy field crews to capture the maximum amount of useful data per hour expended. Their methodology tests the map unit composition for the identified components. If well organized, they eliminate a field crew's need to look for representative sites (or temptation to avoid undesirable types, such as bramble thickets).

- v. *Stratified random design.* A stratified random sample is obtained by forming classes, or strata, from within the inventory area and then selecting a simple sample from each (Barber 1988). Select stratification criteria and apply to the study area. The most common stratification is the ecological map unit component. Within a designated stratification, randomly generate the spatial coordinates for sample location sites. Navigate to the assigned coordinates using Global Positioning System (GPS) technology. Establish a rule base for handling access problems, disturbance areas, and other situations that alter sample design layout.

Note: This design is best suited for inventory areas with less variance or heterogeneity in ecological map unit components. At broader scales, or in highly complex landscapes, the randomness of this procedure may introduce error when the sample size is inadequate to capture the diversity of the landscape. This sample design is most statistically defensible and advantageous when an adequate number of sites are sampled to capture the variation within a given stratification.

- 8. Select sampling location.
 - a. For representative sampling design, select a sampling site that reflects the central concept (i.e., typical condition observed) of the map unit and its components. Care should be taken to avoid micro features or ecotones.
 - b. For random sample designs and transects, do not avoid micro features or ecotones.

-
9. Select an area to test the legends, verify initial delineations, and map unit concepts.
 - a. Perform site characterization by collecting data at integrated plot sites and other observations according to established protocols.
 - b. Complete mapping of the selected area based on information collected during the field sampling, verification, correlation, and quality control processes.
 - c. The steps above are iterative. Extrapolate map unit delineations to areas of high confidence.

Note: The mapping process and field sampling process may be interactive or may occur independently in stages. Important influencing factors include the time of year of mapping, the experience and training of delineators, and the adequacy and completeness of existing TEUI information. In the beginning, the process is generally more interactive with a small amount of delineation followed by field sampling. This process continues until the mappers are comfortable with their ability to accurately photo interpret and extrapolate map unit concept and component concepts of the TEU. As mapping continues, less field verification will be necessary.

10. Track, refine, and correlate ecological units, components, and type characteristics.
 - a. Track documentation amounts by type of observation, update preliminary legend in a timely manner, revise any taxonomic changes, and track all correlation decisions.
 - b. Update map units to approved status when all documentation requirements have been met.
 - c. Check map unit composition through visual inspection and supplemental transects to verify and refine map unit composition estimates.
 - d. Merge or correlate ecological units, components, and ecological types that have similar characteristics, composition, and management interpretations. For example, as new mapping areas are visited in the field, the number of ecological units increases. As they are added, each new unit is progressively checked for significant differences with similar established units. As more map units are added, their properties overlap those of competing units. Correlation maintains significantly different ecological units, while reducing the number of units that have similar management implications, capabilities, and composition.

11. Perform quality control.

- a. Perform quality control checks on mapping, documentation, sampling procedures, and the accuracy and precision of estimates. Ensure TEUI and NCSS standards are met. Design the checks to be carried out during the work plan development process, and progressively during the mapping and classification process. Quality control checks range from scheduled field reviews to daily assists. The mapping team has the primary responsibility of ensuring the application of quality control.
- b. For additional instruction see 3.5.5 Correlation of Ecological Types and Units, 3.5.3 Quality Control and Assurance, and 3.5.4 Quality Control/Assurance Roles and Responsibilities.

12. Enter Data.

- a. Progressively enter data into the NRIS Terra database. Additional regional tables may be needed to ensure more localized interpretations needs are satisfied.

13. Document map units.

- a. Develop block diagrams depicting map unit concepts.
- b. Collect photographs to catalog and document landscapes, vegetations, soils, and geologies.
- c. Assign appropriate classifications.

14. Finalize mapping and classifications.

- a. Finalize legend.
 - i. The legend is considered finalized when all mapping is complete, no new map units are to be added, and no changes are going to be made to ecological types or ecological unit components.
- b. Finalize mapping.
 - i. Match adjacent LT mapping. The completed LT maps should be joined to adjacent survey areas. A quality join must be maintained along the survey boundary. Accomplishing a quality join requires that the map unit delineations, attributes, and interpretations match across the boundary.

-
- ii. Compile mapping onto a stable base. Compilation methods will vary according to specific mapping techniques used on an inventory. Typically, lines are transferred to stable-based Mylar and scanned or digitized into the GIS environment. Alternatively, if onscreen digitizing and/or digitizing tablets are used to maintain or adjust mapping products, this step may not be required.
 - iii. Scan or digitize mapping. All mapping layers should be prepared for scanning or digitizing according to national cartographic standards.
 - c. Finalize any taxonomic classification developments including PNV and ecological type classifications.
15. Finalize descriptions for ecological units and ecological types.
- a. The descriptions of all mapping products are considered final when no subsequent changes are to be made during the current mapping effort.
 - b. Examples of ecological unit and ecological type descriptions are provided in appendix F.
16. Develop interpretations.
- a. Interpretations are to be developed for the ecological types, ecological unit components, and the ecological unit as determined during the work plan development process. The most common interpretation is made on the ecological unit component, as it has the least variability, the easiest field recognition, and most meaningful management implications at the given mapping scale.
 - b. Standard interpretations for soils are provided in the *National Forestry Manual* (USDA NRCS 2000) and the *National Soil Survey Handbook* (USDA NRCS 2003b).
17. Prepare manuscript.
- a. An example of a manuscript format is provided in appendix F.

Mapping Alternatives

The following alternatives are suggested approaches for mapping the TEU. Choose an appropriate method following the evaluation of individual survey areas described in table 1.5.

Because each situation will be unique, the following list is a guideline. The best alternative may be one or a combination of the following alternatives and should be selected after discussion with the regional TEUI specialist.

Crosswalk Existing Mapping

Develop a list of soil survey map units and the new ecological map units to which they correspond, taking care that all ecosystem elements are adequately incorporated and described. Begin with existing delineations. Retain those delineations that meet TEUI criteria. Document those delineations that do not meet TEUI criteria or NCSS standards and propose changes to the original mapping, and/or develop a plan to gather supplemental data to meet TEUI documentation requirements.

It may be possible to make the majority of drafting changes onscreen using DEMs, DOQs, a Landsat Thematic Mapper, and other TEUI tools to help identify where changes are obvious on the original soil survey.

Update Existing Mapping

Use photos or remote sensing as a background with the original soil survey or other ecological unit inventory mapping to evaluate delineations for TEUI landscape elements. Make changes to the original mapping as needed on overlays or onscreen. New polygons must be documented and correlated to existing or new map units, ensuring that all data standards are met.

Conduct New Mapping

Follow the procedures outlined in sections 2.3.1 and 3.2.2 to delineate TEUs.

The cost effectiveness and timeliness of these alternatives should be compared against starting over with a new legend. One recommended method is to randomly select a small area or subset of the inventory area and revise the mapping as needed to meet TEU objectives. Compare the new map to the existing map and evaluate the cost of the revision with the gain of additional information and increase in interpretation accuracy. Determine the cost-benefit relationships of proceeding with the given alternative, and develop the work plan according to the selected alternative.

3.2.3 Existing Information Sources

Base Maps

Primary Base Series Maps

Primary base series maps are large-scale USDA Forest Service maps constructed from U.S. Geological Survey (USGS) topographic quadrangle maps. In addition to the information carried on USGS maps, primary base series maps contain additional USDA Forest Service information such as protracted Public Land Survey System landlines, ownership, USDA

Forest Service route numbers, administrative boundaries, and facilities. For more information, visit <http://fsweb.gsc.wo.fs.fed.us/>.

Aerial Photography

Aerial photography may be used as a base map as well as for field reference. Common types of aerial photography include natural color, infrared, and large format. Using stereo pairs to view landscapes in three dimensions can help interpret landscape elements.

The Aerial Photography Field Office (APFO), Farm Service Agency, is the primary source of aerial imagery for the U.S. Department of Agriculture. More than 10 million images are stored by the APFO, dating from 1955 through the present. For more information, visit <http://www.apfo.usda.gov>.

The National High Altitude Photography program, initiated in 1980, is coordinated by the USGS to acquire aerial photography of the 48 conterminous States every 5 years. Visit <http://edc.usgs.gov/Webglis/glisbin/guide.pl/glis/hyper/guide/napp>.

Digital Orthophoto Quadrangles

A DOQ is a digital representation of an aerial photograph with ground features located in their true positions. Displacements in imagery caused by camera tilt, sensor orientation, and terrain relief are removed. DOQs combine the image characteristics of a photograph with the accuracy and scale associated with a map. Though they cannot be used for stereo interpretation, they are an excellent digital base map for onscreen digitizing or review of registration. For more information about DOQs, visit <http://fsweb.gsc.wo.fs.fed.us/>.

Digital Elevation Models

A DEM is a digital data file containing an array of elevation information over a portion of the Earth's surface. This array is developed using information extracted from digitized elevation contours from primary base series maps. For more information, visit <http://fsweb.gsc.wo.fs.fed.us/>.

Satellite Imagery

A variety of satellite imagery is available through the USGS National Center for Earth Resources Observation and Science at <http://edcwww.cr.usgs.gov/>.

The Remote Sensing Application Center (RSAC) at <http://fsweb.rsac.fs.fed.us/> is a detached Washington Office Engineering Staff unit located in Salt Lake City, UT. The mission of RSAC is to provide technical support to USDA Forest Service resource specialists and managers in the use of remote sensing, image processing, GIS, and related geospatial

technologies for all resource applications. RSAC is collocated with the USDA Forest Service Geospatial Service and Technology Center and the USDA APFO.

Use of Existing Inventories

TEUI Evaluation Criteria

An existing inventory meets the basic requirements of TEUI at the land unit scale if it meets the following criteria:

- Soils and ecological types have been correlated within subregion and/or major land resource areas.
- The inventory must use integrated plots as the basis for ecological types. Integrated plots are defined in section 3.3.1.
- Plots must be geospatially located on aerial photos or on a GIS point layer documentation of map units.
- Plot data must be available either as hard copy or electronically.
- An ecological type classification must have been developed according to the methods described in “Use of Soil Surveys” below.
- Ecological type and TEU LT documentation must meet standards as defined in table 3.3.
- Sampling intensity needs must be determined according to table 2.5, with intensity levels that meet the needs of the users.
- Map unit components are described as ecological types.
- Soil classification, description, and documentation meet NCSS standards. See 1.5 Soil Survey Program.

Updating Existing Inventories

Additional fieldwork and analysis are often necessary to meet the above requirements. For example, vegetation, geologic, and geomorphic information should be collected to the standards described in this technical guide to supplement soil descriptions and create ecological types. When soil sample site data cannot be spatially located, collection of additional soil data is required. Every effort should be made to supplement existing data at the exact location where they were originally collected.

Use of Soil Surveys

One of the first decisions to be made in mapping the TEUI is the extent to which existing or ongoing soil surveys will be used. Soil surveys must be evaluated according to the following criteria:

1. Do they meet current NCSS standards as described in this technical guide?
2. Do they meet additional TEUI criteria and standards for geology, landform, and PNV as described in this document?
3. Can ecological type classifications be created using the data available to the soil survey?

The evaluation of a soil survey includes an evaluation in two categories: written documentation (map unit and taxonomic unit descriptions) and maps or delineations. A primary consideration is an acceptable correlation between the map unit descriptions and the actual polygon delineations and their supporting data.

The evaluation process requires knowledge of local conditions (or access to someone who can provide this knowledge), a familiarity with photo interpretation and mapping, and an understanding of soil survey maps and information and how they were developed. As a minimum, the regional TEUI coordinator, TEUI project leader, and forest soil scientist should be involved in this review. The regional ecologist and forest ecologist should also be consulted.

Additional Evaluation Criteria

Evaluate each soil survey map unit description to determine the extent to which geology, landform, and PNV elements have been incorporated and described. Select a representative sample of delineations from the soil survey area for comparison with map unit descriptions. Aerial photographs must be used to evaluate delineations for the landform component. Aerial photos with the original mapping are most desirable.

From this observation, establish the adequacy of the map unit description for geology, landform, and PNV, compared to the standards described in this technical guide. Evaluate the accuracy of map unit boundaries and the concept of each mapping unit.

Evaluate polygon size. Polygon size should be appropriate to the guidelines for the TEUI. Polygons that are larger than the size recommended should be evaluated to determine if more detail is needed. Polygons that are smaller than the size recommended, particularly

less than 6 acres, should be evaluated to determine if they are already recognized as “included,” “other,” or “similar” in another map unit, and for consistency and accuracy of delineation.

Consider the following questions:

- Does the map unit description include all TEUI elements? Does enough data exist to create ecological types from the map unit descriptions? Are inclusions adequately described for each map unit? Does the map unit description include the interrelationships among components where they can be determined? Are the scale of mapping and size of polygons consistent with the TEUI? Are riparian areas and wetlands delineated according to the TEUI size criteria?
- For geology: What is the source of the geology information used in the soil survey? Is more detailed or updated information available that was not used in the soil survey? Do the soil survey map units and components adequately describe lithology and/or parent/surficial materials? Are the interrelationships between geology and other landscape elements described?
- For landform: Does the soil survey map unit describe landforms? Can the landforms described be crosswalked to the valid values listed in this technical guide? Do soil survey polygon delineations correlate well with descriptions of landform in the map unit? Do delineations of the same map unit consistently identify the same landforms? Are the landforms listed consistent with their related parent material descriptions? Can landforms be combined or aggregated to meet the inventory’s purpose?
- For PNV: Do soil survey map units describe PNV? Are relationships to soils and microsite established where possible? Are the variability and level of description acceptable for TEUI mapping (i.e., information appropriate to scale)? Do polygon delineations correlate well with descriptions of PNV in the map unit? Are there species lists and indications of species composition at site locations?

Use of Riparian Inventories

Evaluate existing riparian inventories to determine whether they meet TEUI polygon delineation criteria. Transfer existing riparian delineations that meet TEUI criteria to either aerial photos or the prepunched, matte Mylar. Either riparian polygons should be correlated with existing TEUs or new map units should be proposed and documented.

Figure 3.3. *Original soil survey mapping with image in background.*

Figure 3.4. *Black lines represent new delineations meeting TEUI criteria.*

Figure 3.5. *Final TEUI map.*

Incorporation of Valley Segments

Where valley segments have been identified as part of the Aquatic Ecological Inventory, they should be incorporated into TEU mapping.

3.2.4 Work Plans

For LTs and LTAs, execute the following major planning steps:

- Establish memorandum of understanding (MOU) to specify the conduct of TEUI with cooperating agencies. As a minimum, the MOU must address the management and administration of the soils portion of the TEUI and address NCSS standards for classification, description, and documentation.
- Identify primary users of the inventory data. The needs of users affect the design of map units and guide the style of reports.
- Collect and evaluate existing information pertinent to the inventory area, such as previous soil resource inventories, plant community classifications, landform descriptions, and geology legends.
- Determine inventory leadership responsibilities. Verify assignments and clarify understandings between soil scientists, ecologists, and others on the size, purpose, procedures, and products of the inventory. Identify the what, where, who, when, and how to do the job. Document the assignments in the TEUI work plan or the memorandum of understanding.
- Ensure that data collection plans are consistent with the objectives and required standards of the inventory.

-
- Evaluate adequacy of personnel (time and expertise), equipment, and funding to accomplish the work. Analyze methods (detailers, helicopters, contracting). Clarify management needs for successfully accomplishing the inventory.
 - Schedule periodic quality control and assurance reviews.

Work Plans for Inventory Areas

Prepare work plans for all TEUIs. Submit work plans to the regional office for approval/review and incorporation into the region's Inventory and Monitoring Program Plan. In addition to serving as a record of purpose, the work plan provides specifications, participant responsibilities, report plans, and a general work schedule. The work plan also provides the participants with a common understanding of the product to be produced, and guides ecologists, geologists, and soil scientists in organizing and conducting the inventory. The content of a work plan should include the elements described below.

Purpose for Doing the Work

Specify inventory objectives with sufficient detail to support recommended inventory intensity and map unit design. The main objective is to produce a product for current and future resource management and forest planning needs. It must be cost efficient and maintain technical integrity of mapping procedures. Determine specific information requirements by consulting potential users and other specialists, and by reviewing pertinent documents such as the forest plan. Coordinate with other resource specialists to design the inventory to meet multiple needs for information. When survey areas contain large areas of land with different management direction, develop objectives for each area. For example, an area that contains classified wilderness and intensively managed forest will generally require an inventory with two different sampling intensities, map scales, and mapping techniques. The mapping detail should be identified. Use inventory sampling intensity levels as defined in table 2.5.

Description of the Work Area

Describe location, physiography, climate, and vegetation of the inventory area. State the ownership and acreages of lands to be inventoried. Supply a general location map.

Cooperating Agencies and Their Responsibilities

List responsibilities of, and expected contributions from, cooperating agencies, if applicable.

Specifications and Plans

Develop specifications consistent with the objectives of the inventory. Accomplish ecological map unit design and interpretations in an interdisciplinary manner. Identify disciplines and expertise necessary to assist in this effort. Include scientifically defensible methods for data collection needed to describe potential and existing vegetation, soil, topographic features, geology, landform, hydrologic function, and climate information significant for management. Describe classification systems and data analyses to be used for these elements, and procedures for integrating these data into ecological type classifications.

Describe additional needs including map compilation and finishing, word and data processing, and contracting specifications. Identify the final products. Describe manuscript format and content. Identify map scale. Establish timeframes and assign responsibility for manuscript preparation, review, and distribution. Specify plans to consolidate and/or incorporate mapping from other inventory areas to meet management needs.

Special Studies

Work plans should include specifics of special studies conducted to supplement needed survey information. Some examples of special studies may include soil temperature and moisture, management responses, geomorphic studies, botanical sampling, and soil chemical analysis.

Signature Blocks

Include appropriate signature blocks for approving officials.

Memorandum of Understanding

Develop MOUs as appropriate to document the relationships and expectations of agencies involved in TEUI.

Annual Plan of Operation

The annual plan of operation serves as the guide for inventory progress measurements during quality control reviews. It is developed annually as progress brings inventory into new stages of the work plan. Include the amount of work completed and an appraisal of the remaining work. Estimate time required to complete inventory and schedule work for the current fiscal year. Include targeted acres, amount, and kind of supporting data, sampling for lab analysis, interpretation development, a schedule of reviews, plans for report writing and map finishing, and training of personnel and resource managers.

Inventory and Monitoring Program Plan

TEUIs should be incorporated into the region's Inventory and Monitoring Program Plan. The Inventory and Monitoring Program Plan is developed to support assessments, forest plan revisions, and determine program needs. The plan also is used to develop a realistic forecast of national needs and provides a basis for program accountability and funding of inventories.

Note: See section 3.6.2 for further description of the Inventory and Monitoring Program Plan.

3.2.5 Logistics

Schedule

Consider local weather patterns, timing of snowmelt, runoff, and greenup of vegetation when scheduling field activities.

Facility and Equipment Needs

Office Space

Office space for the TEUI crew should be located as close to the survey area as possible and include sufficient room for light tables, desks, and access to Government computers and networks for data acquisition. Ideally the crews will share the same work area to facilitate communication of classification and mapping concepts.

Field Camps

Field camps may need to be located at facilities closer to the sampling areas, including ranger stations, work centers, guard stations, campgrounds, or other government facilities. Sometimes it may be necessary to set up spike camps to access very remote areas. Accessing such areas may include travel by all-terrain vehicle, by four-wheel-drive vehicle, by boat, on foot, on horseback, or by helicopter. Planning of such trips requires that all crew members have a thorough knowledge of the area including access points, landmarks, trails, and landing zones, and must also take into account safety concerns of backcountry travel. These concerns may include, but are not limited to, steep and rugged topography; weather-related hazards such as lightning, flooding, extreme heat or cold; and the potential for incidents with dangerous animals.

Field Equipment

A complete list of equipment and sources can be found in appendix H.

Hardware and Software Requirements

Field offices should have the most recent corporate hardware and software upgrades including requirements for the NRIS Terra database and the TEUI Geospatial Toolkit.

Personnel Requirements

TEUI Team Expertise and Makeup

TEUI field crews must have expertise in geology, soils, climate, plant taxonomy, and ecology. The TEUI requires expertise in conducting a systematic (cause/effect) evaluation of the relationships among the elements that make up the ecological types. Team members must be able to conduct analyses that integrate those landscape elements into ecological types.

The TEUI team is typically composed of a project leader and crew members with the skills described above. The project leader should have adequate experience conducting TEUI, supervision, and program management. Crewmembers should be specialists in at least one of the above disciplines, but a crew will not always have a specialist representing each field. The TEUI team should also have expertise in GIS and database analysis.

Training and Qualifications

Each team member will have a training and development plan. Suggested training plans and courses are listed in appendix I.

Job Descriptions

Examples of job descriptions are available in appendix I.

3.3 Data Collection

3.3.1 Field Data Collection—Standards and Methods

Integrated Plots

Data must be collected in an integrated manner. Vegetation, soils, landform, surficial geology, and bedrock, where available, must be fully described for every sample site used to establish an ecological type and document a map unit.

At a sample site, a plot should be uniform in environment and vegetation, and large enough to include the normal species composition of the stand. The vegetation must be homogeneous over a large enough area to completely include the sample plot. Obvious ecotones, or sites lacking environmental uniformity, are not suitable for sampling.

The sample site should exhibit minimal effects of historical land use or recent disturbance. Some sites initially targeted for sampling will prove to be unsuitable when examined in the field. Acceptable sample sites include the following criteria:

- Minimum age for the overstory.
- Minimum canopy closure for forested types.
- No evidence of old homesteads, roads, fields, etc.
- Absence of exotics and low abundance of early successional species in the understory.
- Minimal evidence of recent cutting, thinning, underplanting, grazing, or other management-related disturbance.

Required and Optional Fields (Attributes)

Core attributes represent the minimum plot level data required to meet the national TEUI protocol. See 3.3.2 Field Forms and 3.3.3 Integrated Plot Standards for required core attributes or data standards.

Optional attributes are those identified as commonly desired by many regions to facilitate classification and characterization, or to develop interpretations. Optional attributes recognized by the TEUI protocol are included to lend credibility, database support, and standardization of these attributes. Regional TEUI program managers may choose to upgrade certain optional attributes to required attributes (core) for their region.

All core attributes in the national TEUI protocol will be supported in the NRIS Terra database and follow national standards. Support means that data entry and edit forms are provided and applications and reports will be developed to use this information. All optional attributes recognized in the national TEUI protocol can be accommodated in the NRIS Terra database. Data entry screens and database fields can hold this information. Corporate tools, however, will be driven largely by corporate or core data. Data collected at a region's discretion beyond the core and optional attributes listed in this document may not necessarily be accommodated in the NRIS Terra database and might not follow a national standard. Coordinate with regional and national stewards on such matters.

3.3.2 Field Forms

The following TEUI forms organize the elements of TEUI based on theme:

- **General Site Data Form.** Data recorded on this form describe basic information about the site such as location, examiners, slope, elevation, ground cover, etc. This information is collected for both integrated plots and observation sites.
- **Ocular Macroplot Form.** This form contains a basic set of field attributes that characterize vegetation composition and structure at integrated plots to support ecological classification.
- **Tree Measurement Form.** This form is used to record data for individual tree measurements. This type of data should be collected where appropriate to derive productivity, stand structure, and related interpretations.
- **Geologic and Geomorphic Forms.** These forms contain attributes on geologic and geomorphic data that characterize the site.
- **Soil Pedon Description Forms.** These forms contain a detailed set of soil pedon data that characterize the site.

The NRIS Terra database houses the data from the above field forms. Data is entered through the NRIS Terra module using ORACLE forms. Instructions are found in the <http://fsweb.sandy.wo.fs.fed.us/terra/>.

Use of Other Forms

The TEUI field forms in this document were developed in conjunction with TEUI and NRIS personnel. All data items on all forms can be entered into the NRIS Terra database unless otherwise noted. Regions may choose to use an alternate form, condense the TEUI forms, or alter form layout as long as core data fields are maintained. For example, a region may choose to print forms that show only the fields required for that region (national core plus optional fields determined by region). The data entry forms in the NRIS Terra database, however, closely emulate the field form layout and column order as presented in this document.

3.3.3 Integrated Plot Standards

Standard methods of data collection for soil, geology, geomorphology, and vegetation are referenced or described below.

Sample Site/Plot Locations

Sample site data should be located on air photos by a pinprick identifying the location of the integrated plot and the sample site ID should be clearly labeled in permanent ink on the back. A point layer should then be created. The point layer may be developed by using DOQs as a background for onscreen digitizing, transferring the point from the photo to a Mylar overlay and digitizing, or by building the layer electronically using GPS coordinates recorded in the field. The sample site ID is then entered into the database along with the plot information.

Care should be taken to compare GPS-derived sample site locations with points on the photos or base maps. Because of poor GPS satellite configurations or GPS reception, accuracy of GPS-derived locations may be lower than the location as determined manually in the field. These areas are readily discovered when the GIS point coverage from the GPS coordinates is crosschecked with the locations on the photos or base maps.

Soil Data

Soil pedon data is collected according to NCSS standards. Use codes and procedures in the NRCS publication *Field Book for Describing and Sampling Soils* (Schoeneberger et al. 2002). A soil pedon data form, instructions, and codes are also included in appendix E. For landforms and parent materials, use terms in appendix D. Soil and map unit data are entered into corporate systems.

Geologic Data

Geologic information should be collected according to the standards in the Forest Service Manual 2881. Describe surficial geology origin and kind using the terms and definitions listed in the NRIS Terra data dictionary. Also note depth to bedrock where observed.

Geomorphology

Geomorphic information is collected to the standards in *A Geomorphic Classification System* (Haskins et al. 1998). That volume also describes how to collect the morphometric characteristics listed in table 2.8. Data types and valid values are listed in appendix D. At a minimum, plot locations will be assigned a classification from the list of hierarchy geomorphology classes in appendix E to describe the dominant, active landform-process relationship.

Vegetation Data

Several general methods have been identified as acceptable for collecting vegetation cover data at the scale appropriate for classification of ecological types. These methods include ocular macroplots; multiple small plots or frames; and variable-radius plots (used for determining density and basal area of live trees and snags).

Presampling tests should be conducted to determine minimum plot size and number of replications needed to capture the variability of the site. Plot size must equal or exceed the minimal area of the plant community in the stand. The required minimum plot size varies within wide limits, depending on vegetation formation and stratum. The actual size needed can be determined from a minimum area curve (i.e., by plotting number of species against plot size). As a rule of thumb, a single representative plot meets the minimal area requirements when enlarging the plot adds no or very few new species. Plots larger than the minimal area provide acceptable data but are less efficient in terms of resources required to accomplish the sampling. If plots are too small, floristic data will not be adequate for developing a vegetation classification. Distinct advantages often exist to using different plot layouts depending on site conditions, types and amounts of vegetation, and variability of vegetation.

3.4 Data Storage

Natural Resource Information System Terra

Map unit, component, and ecological type data are entered in the NRIS Terra database. Specific instructions and help are available in the NRIS Terra data entry guide and online in the database application at <http://fsweb.sandy.wo.fs.fed.us/terra/>.

Geographic Information System Data Dictionary

GIS layers for the LT and LTP levels meet the requirements in the GIS data dictionary. Visit <http://fsweb.wo.fs.fed.us/im/standards/gis/coredata/> for more information. GIS layers include the following elements:

- Polygon coverage composed of map units.
- Line coverage.
- Point coverage containing point locations of integrated plots.

National Soil Information System

Data to be entered in NASIS will be governed by the MOU and work plan. As a minimum, field units must provide soils documentation (USDA NRCS 2003b, part 627.08) to NRCS for correlation purposes, with the exception of a soil map.

3.5 Analysis

3.5.1 Data Summaries

Typical data summaries for map units include acres, slope, elevation, aspect, curvature, number of plots, etc. Typical summaries for components include location of integrated plots and type location, ranges in characteristics and properties for soils, vegetation, geology, geomorphology, and slope shape.

3.5.2 Synthesis and Interpretation

Data Analysis to Develop Vegetation Classifications

The entire vegetation classification process, from initial literature review to final published classification, is outlined in section 2.21 of the *Existing Vegetation Classification and Mapping Technical Guide* (Brohman et al. 2005). We focus here on the data analysis step of their process. Discussion is limited to potential vegetation, and assumes familiarity with basic concepts of statistics such as whether data are normally distributed or non-parametric, measures of variance and central tendency, etc. We will further assume that the objective of analysis is to identify patterns in vegetation community data to classify those communities, and then use environmental data (slope, aspect, soil depth, etc.) to relate those communities to environmental gradients. (For examples, see Spies and Barnes 1985, Shumar and Anderson 1986, or McCay et al. 1997). Cleland and Ramm provide a useful, concise literature review of multivariate analysis techniques used in ecological classification (<http://www.ncrs.fs.fed.us/gla/reports/ecs-methods.pdf>). The reader is also strongly advised to obtain and study *Analysis of Ecological Communities* (McCune et al. 2002) as a guide to the analysis of vegetation community data.

Such analysis goes beyond basic statistical analysis in that it involves many variables (hence multivariate analysis), and we often look for consistent patterns in vegetation abundance rather than compare means. The work, therefore, takes on a descriptive as well as analytic nature. Furthermore, one concise answer does not generally arise from this iterative process that classifies the data with more and more confidence as successive analysis shapes a clearer picture of how the data should be grouped—and how consistently it relates to realities on the ground. Classification is a skill that develops over months.

Figures 3.6 and 3.7 provide useful flowcharts to outline the data analysis process. Figure 3.6 shows that the data are first entered, checked, and cleaned. Ensure that data are entered in a format consistent with the data analysis software package. This time-consuming process can be greatly simplified by using field data recorders.

Figure 3.6. Typical analysis flow for community data. Figure courtesy of Jeri Peck, *Ecostats*.

Figure 3.7. *Selecting an analysis technique. Figure courtesy of Jeri Peck, Ecostats, and Bruce McCune, Oregon State University.*

Data are then summarized to get some basic ideas about the data set. Data used to develop vegetation sets typically consists of a species abundance by plots matrix. The plot numbers can identify the rows of species abundance data, with one column for each species. (Alternately, the columns can be plot numbers with one row for each species, known as a transposed matrix.) The count of species, the number of times a species occurs, its average cover, and the range in its cover values are all data summaries typically generated for a data set. Another value of generating a summary is that rare species (those occurring only a few times or less) can be identified. Excluding rare plant data from an analysis often will improve the results because rare occurrences of a species can distort the patterns generated in clustering and ordination routines.

Identifying outliers is related to identifying rare species. Outliers are data points with values far outside the normal range of data variation (more than two standard deviations from the mean is a common rule of thumb). Outliers can greatly skew results and distort plant community data patterns. Software programs can identify outliers. When analysis seeks to identify vegetation patterns, removing outliers from a data set is desirable and is not cheating. We are not looking for significant differences between means, but instead discerning the significance of patterns.

Transformations are also useful during the data preparation process, particularly with environmental data such as slopes, elevations, aspects, tree basal area, etc. If we are comparing tree basal areas ranging from 20 to 160 square feet per acre with elevations that run from 900 to 4,600 feet above sea level, the difference in units and the difference in scales can distort results. In these cases, it is desirable to normalize the data by converting all variables to the same scale but using each value as a percent of the total possible value in its range.

Another common transformation is the arcsin transformation, where percent data is converted to a decimal number to approximate a normal distribution. Aspect data are transformed using the formula in Beers et al. (1966). Other transformations are possible. We aim to standardize and normalize data when necessary, not change it so we get a more desirable answer.

After the completion of these data preparation steps, we are ready to begin analysis. Summaries are a good first step. Species in a species-plot matrix can be summarized by how often they occur, their average occurrence, and their range of values. Sort them by lifeform, listing the overstory tree species first, then the understory trees, followed by shrubs, and then the herbaceous layer. Another value of summarization is that species that seldom occur in the data set can be excluded from future analyses. As with excluding outliers, excluding these uncommon species can avoid distortions.

Analyses now fall into two groups: clustering and ordination. A variety of analysis programs can perform these routines, and are detailed in McCune et al. (2002). Figure 3.7 provides some guidelines on selecting analysis techniques. Note that each method has its strengths and weaknesses. A variety of analysis methods should be used, and if they generate roughly the same result, a correct picture of the ecological reality is probably being developed. In contrast, a method that gives starkly different results from most other methods would be strongly suspect and could be discarded.

Clustering, in which samples are grouped by similarity, is generally performed first. In the more sophisticated ordination analysis, samples are arranged (or ordinated) along axes of ecological space based on the multiple relationships of the plant species and their abundances to each other. The strength of these relationships is measured with eigenvalues. High eigenvalues mean a good deal of variation is being explained by the ordination. The axes of the ordination generally correspond to environmental gradients. Elevation and available moisture are two common gradients explaining most of the variation in a data set. Canonical correlation can be used to formally relate these axes to environmental attributes; with other ordination programs (such as correspondence analysis and multidimensional scaling), these relationships are only inferred.

Interpretations

Interpretations can be developed by selecting appropriate attributes for analysis and display and/or combining TEU attributes/interpretations with other sources. The following tables are a subset of typical attributes and interpretations commonly derived from the TEU information. Documentation of new interpretations should include what data are used, how they are developed, and what assumptions are made.

Attributes Used for Analysis and Characterization

Table 3.6 provides a list of commonly used LT component data attributes used in analysis, display, and interpretation.

Soil Interpretations

Standard soil interpretations are generated from the NRCS NASIS database and the criteria are documented in the *National Forestry Manual* (NFM), the *National Soil Survey Handbook* (NSSH), and *National Range and Pasture Handbook*. Generally, the criteria may be supplemented for local or regional use. Table 3.7 provides a list of recommended soil interpretations for LTs. All interpretations are based on the soil component and care should be taken when aggregating ratings to the map unit level. When map units have multiple components, percent composition should be used to adjust ratings depicted on GIS map displays and in analysis procedures. Adjustments may include dominant soil component, dominant interpretive condition, most limiting component, least limiting component, or others as appropriate for the interpretive use being considered.

Table 3.6. *Data attributes used in analysis, display, and interpretation.*

Planning and analysis scale	Interpretation/ attribute	Description	Reference
Land unit	Runoff potential	Surface runoff refers to the loss of water from an area by flow over the land surface. The estimation of the amount of runoff is important to hydrologic models in assessing the streamflow and water storage.	NSSH 2002
Land unit	Available water holding capacity	Available water capacity is the volume of water that should be available to plants if the soil, inclusive of fragments, were at field capacity. It is commonly estimated as the amount of water held between field capacity and wilting point, with corrections for salinity, fragments, and rooting depth.	NSSH 2002
Land unit	Drainage class	Drainage class identifies the natural drainage condition of the soil. It refers to the frequency and duration of wet periods.	NSSH 2002
Land unit	Hydrologic group	Hydrologic group is a group of soils having similar runoff potential under similar storm and cover conditions. Soil properties that influence runoff potential are those that influence the minimum rate of infiltration for a bare soil after prolonged wetting and when not frozen. These properties are depth to a seasonally high water table, intake rate and permeability after prolonged wetting, and depth to a very slowly permeable layer. The influence of ground cover is treated independently.	NSSH 2002
Land unit	Erosion hazard	Erosion hazard is the hazard of soil erosion	Defined locally
Land unit	K-factors	Soil erodibility factors (Kw) and (Kf) are erodibility factors that quantify the susceptibility of soil detachment by water. These erodibility factors predict the long-term average soil loss, which results from sheet and rill erosion under various alternative combinations of crop systems and conservation techniques. Factor Kw considers the whole soil, and factor Kf considers only the fine-earth fraction, which is the material less than 2.0 mm in diameter.	NSSH 2002
Land unit	Hydric soil rating	A hydric soil is a soil that formed under conditions of saturation, flooding, or ponding long enough during the growing season to develop anaerobic conditions in the upper part. Hydric soils along with hydrophytic vegetation and wetland hydrology are used to define wetlands.	NSSH 2002
Land unit	Flooding frequency and duration	Flooding is the temporary covering of the soil surface by flowing water from any source, such as streams overflowing their banks, runoff from adjacent or surrounding slopes, inflow from high tides, or any combination of sources. Shallow water standing or flowing that is not concentrated as local runoff during or shortly after rain or snowmelt is excluded from the definition of flooding.	NSSH 2002
Land unit	Organic matter percent	Organic matter percent is the weight of decomposed plant and animal residue and expressed as a weight percentage of the soil material less than 2 mm in diameter.	NSSH 2002
Land unit	Slope stability	Defined locally	

Table 3.7. *Recommended soil interpretations for landtypes.*

Planning and analysis scale	Interpretation name	Description	Reference
Land unit	Potential erosion hazard (road trail)	Potential erosion hazard is the hazard or risk of soil loss from unsurfaced roads/trails.	NFM (1998)
Land unit	Potential erosion hazard (off-road/off-trail)	Ratings indicate the hazard or risk of soil loss from off-road and off-trail areas after disturbance activities that expose the soil surface.	NFM (1998)
Land unit	Soil rutting hazard	Ratings indicate the hazard or risk of ruts in the uppermost soil surface layers by operation of forest equipment. Soil displacement and puddling (soil deformation and compaction) may occur simultaneously with rutting.	NFM (1998)
Land unit	Road suitability (natural surface)	Road suitability is the suitability for using the natural surface of the soil component for roads by trucks for the transport of logs and other wood products from the site.	NFM (1998)
Land unit	Log landing suitability	Log landing suitability is the suitability of the soil at the forest site to serve as a log landing.	NFM (1998)
Land unit	Construction limitations for haul roads and log landings	Ratings reflect limitations for constructing haul roads and log landings.	NFM (1998)
Land unit	Harvest equipment operability	Harvest equipment operability is the suitability for operating harvesting equipment.	NFM (1998)
Land unit	Mechanical site preparation (surface)	Ratings indicate the suitability of using surface-altering soil tillage equipment.	NFM (1998)
Land unit	Mechanical site preparation (deep)	Ratings indicate the suitability of using deep soil tillage equipment.	NFM (1998)
Land unit	Hand planting suitability	Ratings indicate the expected difficulty of hand planting.	NFM (1998)
Land unit	Mechanical planting suitability	Mechanical planting suitability is the difficulty of planting tree or shrub seedlings using a mechanical planter.	NFM (1998)
Land unit	Shallow excavations 620-1	Shallow excavations are trenches or holes dug in the soil to a maximum depth of 5 or 6 feet. They are used for pipelines, sewer, and telephone, and power lines. Trenching machines or backhoes are used to make shallow excavations.	NSSH Interpretive Guide (1993)

Table 3.7. *Recommended soil interpretations for landtypes (continued).*

Planning and analysis scale	Interpretation name	Description	Reference
Land unit	Local roads and streets 620-5	Local roads and streets are those roads and streets that have all-weather surfacing (commonly of asphalt or concrete) and that are expected to carry automobile traffic year-round. The roads and streets consist of (1) the underlying local soil material, either cut or fill, which is called “the sub-grade”; (2) the base material, which may be lime-stabilized soil, cement-stabilized soil, gravel, or crushed rock; and (3) the actual road surface or street pavement, which is either flexible (asphalt), rigid (concrete), or gravel with binder in it. They are graded to shed water, and conventional drainage measures are provided. With the probable exception of the hard surface, roads and streets are built mainly from the soil at hand.	NSSH Interpretive Guide (1993)
Land unit	Roadfill 620-7	Roadfill consists of soil material that is excavated from its original position and used in road embankments elsewhere. The evaluations for roadfill are for low embankments that generally are less than 6 feet in height and are less exacting in design than high embankments, such as those along superhighways. The rating is given for the whole soil, from the surface to a depth of about 5 feet, based on the assumption that soil horizons will be mixed in loading, dumping, and spreading. Criteria, limits, and restrictive features for rating soils for local roads and streets are provided in the NSSH (1993). Soils are rated as to the amount of material available for excavation, the ease of excavation, and how well the material performs after it is in place.	NSSH Interpretive Guide (1993)
Land unit	Sand source 620-8	Sand as a construction material is usually defined as particles ranging in size from 0.074 mm (sieve #200) to 4.75 mm (sieve #4) in diameter. Sand is used in great quantities in many kinds of construction. Specifications for each purpose vary widely. The intent of this rating is to show only the probability of finding material in suitable quantity. The suitability of the sand for specific purposes is not evaluated.	NSSH Interpretive Guide (1993)
Land unit	Gravel source 620-9	Gravel as a construction material is defined as particles ranging in size from 4.76 mm (sieve #4) to 76 mm (3 inches) in diameter. Gravel is used in great quantities in many kinds of construction. Specifications for each purpose vary widely. The intent of this rating is to show only the probability of finding material in suitable quantity. The suitability of the gravel for specific purposes is not evaluated.	NSSH Interpretive Guide (1993)
Land unit	Topsoil 620-10	The term “topsoil” has several meanings. As used here, the term describes soil material used to cover an area so as to improve soil conditions for the establishment and maintenance of adapted vegetation.	NSSH Interpretive Guide (1993)
Land unit	Soil reconstruction material for drastically disturbed areas 620-11	Soil reconstruction of areas drastically disturbed, as in surface mining, is the process of replacing layers of soil material or unconsolidated geologic material, or both, in a vertical sequence of such quality and thickness that a favorable medium for plant growth is provided.	NSSH Interpretive Guide (1993)

Table 3.7. *Recommended soil interpretations for landtypes (continued).*

Planning and analysis scale	Interpretation name	Description	Reference
Land unit	Camp areas 620-12	Camp areas are tracts of land used intensively as sites for tents, trailers, campers, and the accompanying activities of outdoor living. Camp areas require such site preparation as shaping and leveling in the areas used for tents and parking areas, stabilizing roads and intensively used areas, and installing sanitary facilities and utility lines. Camp areas are subject to heavy foot traffic and some vehicular traffic.	NSSH Interpretive Guide (1993)
Land unit	Picnic areas 620-13	Picnic areas are natural or landscaped tracts used primarily for preparing meals and eating outdoors. These areas are subject to heavy foot traffic. Most vehicular traffic is confined to access roads and parking lots. Soils are rated on the basis of properties that influence the development costs of shaping the site, trafficability, and the growth of vegetation after development.	NSSH Interpretive Guide (1993)
Land unit	Paths and trails 620-15	Paths and trails are used for walking, horseback riding, and similar uses and require little or no cutting or filling. The soils are rated based on the properties and qualities that influence trafficability and erodibility.	NSSH Interpretive Guide (1993)
Land unit	Off-road motorcycle trails	Off-road motorcycle trails are primarily for recreational use. Trails for other off-road vehicles may have similar criteria. Little or no preparation is done to the trail, and the surface is not vegetated or surfaced. Considerable compaction of the soil on the trail is expected.	NSSH Interpretive Guide (1993)
Land unit	Pond reservoir area 620-28	A pond reservoir area is an area that holds water behind a dam or embankment.	NSSH Interpretive Guide (1993)
Land unit	Excavated ponds (aquifer-fed) 620-30	An aquifer-fed excavated pond is a body of water created by excavating a pit or dugout into a ground-water aquifer. Excluded are ponds that are fed by surface runoff and embankment ponds that impound water 3 feet or more above the original surface.	NSSH Interpretive Guide (1993)
Land unit	Pesticide loss potential—leaching 620-35	“Pesticide loss potential—leaching” is the potential for pesticides to be transported by percolating water below the plant root zone. Pesticides in ground-water solution are leached from the soil surface layer and transported vertically or horizontally through the soil and vadose zone by percolating water. Leaching pesticides have the potential to contaminate shallow and deep aquifers, springs, and local water tables.	NSSH Interpretive Guide (1993)

Table 3.7.—*Recommended soil interpretations for landtypes (continued).*

Planning and analysis scale	Interpretation name	Description	Reference
Land unit	Pesticide loss potential—soil surface runoff 620-36	“Pesticide loss potential—soil surface runoff” is the potential for pesticides to be transported by surface runoff beyond the field boundary where the pesticide was applied. Pesticides are transported by surface runoff as either pesticides in solution or pesticides adsorbed to sediments suspended in runoff. Pesticides that are surface transported have a potential to contaminate surface waters, such as lakes, ponds, streams, and rivers	NSSH Interpretive Guide (1993)
Land unit	Equipment operability for logging areas 620-37	Equipment operability for logging areas applies to the use of rubber-tired skidders in the general logging area, including the yarding area for felled or bunched trees or logs and that extends to a designated skid trail.	NSSH Interpretive Guide (1993)
Land unit	Total tree harvesting 620-40	Total tree harvesting consists of yarding the entire tree to the landing area. Factors considered in rating soils for this practice are the nutrient status of the soil and the effects of removing the tops of trees, which would otherwise be incorporated back into the soil. Also considered is the erosion potential of the soil and the effects of removing slash, which would be a protective factor for the soil.	NSSH Interpretive Guide (1993)
Land unit	Prescribed burning 620-43	Prescribed burning is the deliberate ignition of a combustible material. Foresters use fire to perform three basic functions: consume dead organic material, alter living vegetation, and produce a desired ecological effect. The three functions are not mutually exclusive. Burning dead material inevitably affects the vegetation. The ecological function is, to some extent, a synthesis of other functions. Soil properties are considered in prescriptions for burning not from the standpoint of the actual ignition but from the standpoint of the management objectives of the desired ecological effect.	NSSH Interpretive Guide (1993)
Land unit	Seedling mortality 620-44	Seedling mortality refers to the probability of the death of naturally occurring or planted tree seedlings, as influenced by kinds of soil or topographic conditions.	NSSH Interpretive Guide (1993)
Land unit	Plant competition 620-45	Plant competition is the likelihood that plants other than the desired species will become established during revegetation efforts and that their presence will affect seedling establishment and the growth of desired species.	NSSH Interpretive Guide (1993)

3.5.3 Quality Control and Assurance

Quality control and quality assurance are important at all levels of the TEUI process to ensure that TEUI products are accurate, consistent, and meet the objectives outlined in the memorandum of understanding, work plan, and this technical guide. NCSS standards are required elements of TEUI at the LT and LTP level.

NCSS standards include those for soil classification as found in *Keys to Soil Taxonomy*; those for soil description as found in *The Field Book for Describing and Sampling Soils*; and those for documentation as found in the *National Soil Survey Handbook Part 627.08*, with exception that the TEUI map is substituted for the soil map.

Quality Control

Quality control is the process of providing direction, inspection, and coordination of TEUI activities to ensure that all products meet the defined standards in this guide. The TEUI project leader and crew must ensure that day-to-day activities meet TEUI and NCSS standards.

Quality Assurance

Quality assurance is the process of providing technical standards, review, and training to support TEUI quality control. Quality assurance is the primary responsibility of the regional and national TEUI and NCSS staff.

3.5.4 Quality Control/Quality Assurance Roles and Responsibilities

National

The national TEUI coordinators are responsible for the formulation, coordination, and updates of technical guides and procedural manuals, including the development of national work plans and training courses. Additional responsibilities include setting national policy and ensuring mapping consistency and data quality between regions.

Regional

Regional offices are responsible for the coordination and quality assurance for all TEUI activities including data collection, documentation, interpretation, and correlation. Regional offices will ensure that TEUI meet standards, including NCSS standards, and that documentation is completed and available for correlation. They must ensure the consistency of mapping and data quality between inventory areas, including quality assurance of the data entered into the NRIS Terra database, such as ecological unit, component, site, and geospatial data. In addition, regional offices should compile mapping and complete map unit descriptions at the section and subsection levels of the National Hierarchy.

TEUI Project

The TEUI project staff is responsible for meeting TEUI standards at the LTA, LT, and LTP levels of the National Hierarchy. The TEUI project leader ensures that the proper quality control measures are being conducted by crewmembers. Crewmembers are responsible for ensuring that all data and mapping standards are applied consistently.

3.5.5 Correlation of Ecological Types and Units

Correlation is a process for ensuring consistency in naming, classifying, and interpreting ecological types. The correlation process also provides quality control for consistent description and documentation of the landscape elements.

Field Reviews

Field reviews of TEUIs are scheduled to critically examine design of ecological types and mapped ecological units in the field. The field review serves as a quality assurance procedure to ensure that the database, mapping, classification, and associated documentation of the inventory area meets standards.

The review team leader will give particular attention to the review of soils documentation to ensure NCSS standards are met as outlined in Section 1.5, Soil Survey Program. Field units are encouraged to use progressive correlation for the soils portion of the TEUI, and are required to meet NCSS standards, including documentation necessary for final correlation. TEUI are certified as meeting NCSS standards by NRCS only through a final correlation memorandum (USDA NRCS 2003b).

The TEUI project staff organizes the field review to examine representative map units and sites of major ecological types and units in the area. The field review should also be used to address and correct problems encountered with classification, mapping concepts, and specific needs of the inventory. During this process, the work plan is reviewed and the annual plan of operations is updated. Field review reports are developed by the regional staff and submitted to the regional forester for signature. Any items identified during this process are submitted to the forest supervisor and/or TEUI project office for action.

Review Participants

The field review should include national and regional specialists who have responsibility for each of the landscape elements. Resource specialists and managers familiar with the area, scientists working on nearby ecological unit inventory projects, and representatives of cooperating agencies are encouraged to participate. All field review

participants should be encouraged to state their observations and opinions relative to each ecological type and unit observed, and all discussion should be noted for consideration in making correlation decisions.

Scheduling Field Reviews

Field reviews are to be scheduled as part of the annual plan of operations for each survey area. There should be at least an initial field review at the end of the beginning of the project, one or more progress field reviews during the life of the project, and a final field review at the end of the project.

3.5.6 Mapping and Interpretative Reliability

Accuracy Assessment

The following procedure is a suggested method for performing accuracy assessment of ecological units:

1. Conduct office assessment.
 - a. Assess distributions and ranges of each map unit for environmental variables such as elevation, slope, aspect, and spectral reflectance values.
 - b. Review frequency distribution curves produced from the analysis to determine ranges and variability in the environmental variables.
 - c. Review existing documentation to determine if representative values are within the ranges for these variables.
 - d. Where discrepancies are apparent, refine polygons and use procedures below to conduct field assessment.
2. Conduct field-accuracy assessment for mapping, classification, and description.
 - a. Randomly select 10 percent of the total number of map units for the survey area.
 - b. From the above sample, randomly select individual delineations (polygons) to assess.
 - c. Develop a transect design commensurate with polygon shape and ecological patterns.
 - d. Sample at predetermined intervals according to established intensity levels. At higher intensity levels, more sampling is required to meet the desired interpretative reliability.
 - e. Compare results of sampling to ecological unit and type descriptions.

-
- f. Document results and compare to established standards in the work plan.
 - g. Adjust line work and correlate mapping and taxonomic units as necessary to meet established standards.

3.6 Reporting

3.6.1 Format and Content

NCSS Publications

Publications must meet the minimum requirements as described in part 644 of the *National Soil Survey Handbook* (USDA NRCS 2003b).

3.6.2 Accomplishment Reporting and Scheduling

Report accomplishments by appropriate budget line item and associated activity code.

Appendix A. Glossary

abiotic. Pertaining to the nonliving parts of an ecosystem, such as soil particles, bedrock, air, water (Helms 1998).

abundance. The total number of individuals of a taxon or taxa in an area, volume, population, or community. Often measured as cover in plants (Lincoln et al. 1998).

accuracy. The degree to which a measured quantity approaches the true value of what is being measured (Lincoln et al. 1998).

accuracy assessment. The process by which the accuracy or correctness of an image (or map) is evaluated.

alliance. (1) A grouping of associations with a characteristic physiognomy, and sharing one or more diagnostic species, which, as a rule, are found in the uppermost or dominant stratum of the vegetation (Jennings et al. 2004). (2) A physiognomically uniform group of associations sharing one or more diagnostic (dominant, differential, indicator, or character) species that, as a rule, are found in the uppermost stratum of the vegetation (FGDC 1997).

arc. In GIS, within a spatial context, a locus of points that forms a curve that is defined by a mathematical expression (FGDC 1998).

attribute. One of a set of descriptive terms; a characteristic (Lincoln et al. 1998).

bedrock geology. Characteristics of the consolidated material at the Earth's surface or that immediately underlies soil or other unconsolidated, surficial deposits, specifically lithology (rock type), weathering, structure (e.g., fracturing or bedding), and stratigraphy (the rock-unit age and designation).

business needs. Ongoing tasks related to a particular business or project and the information and other support contributing to the completion of these tasks.

canopy closure. The proportion of ground, usually expressed as a percentage, that is occupied by the perpendicular projection downward of the aerial parts of the vegetation of one or more species. It usually refers to the tree life form of the uppermost canopy, as seen from above, and cannot exceed 100 percent. It is similar in concept to absolute canopy.

canopy cover. (1) The proportion of ground, usually expressed as a percentage, that is occupied by the perpendicular projection downward of the aerial parts of the vegetation or the species under consideration. The additive cover of multiple strata or species may exceed 100 percent (FGDC 1997). (2) The percentage of ground covered by a vertical projection of the outermost perimeter of the natural spread of foliage of plants. Small openings within the canopy are included (SRM 1998, USDA NRCS 1997). Canopy cover is synonymous with canopy closure (Helms 1998). For woody plants, canopy cover is synonymous with crown cover (USDA NRCS 1997, Helms 1998).

canopy cover, absolute. The canopy cover of a species in a plant community, regardless of the presence of other species.

canopy cover, relative. The canopy cover of a species in a plant community, expressed as a percentage of the total cover of all species.

canopy structure. The arrangement of vegetation layers in a plant community.

class. A group of individuals or other units similar in selected properties and distinguished from all other classes of the same population by differences in these properties (Buol et al. 1973).

classification. (1) The process of grouping similar entities together into named types or classes based on shared characteristics. (2) The grouping of similar types according to criteria that are considered significant for this purpose. The rules for classification must be clarified before identifying the types within the classification standard. The classification methods should be clear, precise, quantitative (where possible), and based on objective criteria so that the outcome would be the same whoever performs the definition (or description). Classification necessarily involves definition of class boundaries (FGDC 1997, citing UNEP/FAO 1995).

climax. A self-replacing plant community or species with no evidence of replacement by other plants.

climax plant community. The stable community in an ecological succession that is able to reproduce itself indefinitely under existing environmental conditions in the absence of disturbance. Viewed as the final stage or end-point in plant succession for a site. The climax community develops and maintains itself in steady state conditions.

community. (1) A general term for an assemblage of plants living together and interacting among themselves in a specific location; no particular ecological status is implied. (2) Any group of organisms interacting among themselves (Daubenmire 1978).

community composition. The kinds, absolute amounts, or relative proportions of plant species present in a given area or stand. It can be described qualitatively or quantitatively. The latter may use either absolute amounts or relative proportions of the plant taxa present. The amount of each plant taxon should be expressed as percent cover (FGDC 1997, Jennings et al. 2004).

community type. An aggregation of all plant communities with similar structure and floristic composition. A unit of vegetation within a classification with no particular successional status implied.

component. A subset of an ecological type used to describe the spatial arrangement of an ecological type within the map unit. A component may represent a narrower range of characteristics than the ecological type for which it is named.

composition. (1) The amount or proportion of the plant species on a given area (SRM 1989). (2) A list of the species that comprise a community or any other ecological unit (Lincoln et al. 1998).

constancy. The number of occurrences of a species in a group of plots divided by the total number of plots, expressed as a percentage. All plots must be the same size. For example, if a particular community has 10 plots and a species is found in 8 of the 10, the constancy of that species is 80 percent.

coordinates. In mapping, coordinates are pairs of numbers expressing horizontal distances along orthogonal axes; alternatively, triplets of numbers measuring horizontal and vertical distances (FGDC 1998).

cover. Usually meant as canopy cover that is the gross outline of the foliage of an individual plant or group of plants within a stand or plot. Expressed as a percent of the total area of the plot and may exceed 100 percent if more than one layer is considered. See **canopy cover** and **vegetation cover**.

cover type. A designation based on the plant species forming a plurality of composition within a given area (e.g., oak-hickory) (FGDC 1997). The Society of American Foresters Forest Cover Types (Eyre 1980) and the Society for Range Management Rangeland Cover Types (Shiflet 1994) are examples of cover types.

data element. A logically primitive item of data (FGDC 1998).

delineation. The process of separating map units (repeating sets of polygons) using a consistent set of criteria.

diagnostic species. Any species or group of species whose relative constancy or abundance clearly differentiates one type from another (Jennings et al. 2004). This definition implies that diagnostic species must be determined empirically through analysis of plot data (Mueller-Dombois and Ellenberg 1974).

differential species. A plant species that, because of its greater fidelity in one kind of community than in others, can be used to distinguish vegetation units (Gabriel and Talbot 1984 as cited in Jennings et al. 2004).

differentiating characteristics. Properties selected as the basis for grouping individuals into classes (Buol et al. 1973).

digital elevation model. Digital data file containing an array of elevation information over a portion of the Earth's surface (USDA Forest Service 1999).

digital orthophoto quadrangle. Digital representation of an aerial photo with ground features located in their "true" positions (Clarke 1999).

division. (1) In terrestrial ecological unit inventory, an ecological unit in the ecoregion planning and analysis scale of the National Hierarchy Framework corresponding to subdivisions of a domain that have the same regional climate (ECOMAP 1993). (2) In the Federal Geographic Data Committee (FGDC) physiognomic hierarchy, the level separating Earth cover into either vegetated or nonvegetated categories (Grossman et al. 1998).

dominance. The extent to which a given species has a strong influence in a community because of its size, abundance, or coverage. Strong dominance affects the fitness of associated species (Lincoln et al. 1998).

dominant. An organism exerting considerable influence on a community by its size, abundance, or coverage (Lincoln et al. 1998).

dominant species. The species with the highest percentage of cover, usually in the uppermost layer (Kimmins 1997, as cited in Jennings et al. 2004).

ecological units. Map units designed to identify land and water areas at different levels of resolution based on similar capabilities and potentials for response to management and natural disturbance. These capabilities and potentials derive from multiple elements: climate, geomorphology, geology, soils, water, and potential natural vegetation. Ecological units should, by design, be rather stable. They may, however, be refined or updated as better information becomes available.

ecological type. A category of land with a distinctive (i.e., mappable) combination of landscape elements. The elements making up an ecological type are climate, geology, geomorphology, soils, and potential natural vegetation. Ecological types differ from each other in their ability to produce vegetation and respond to management and natural disturbances.

ecosystem. A functional system of interacting organisms and their environment (Whittaker 1962). Ecosystems have six major attributes: structure, function, complexity, interaction/interdependency, scale, and change over time (Kimmins 1997).

ecotone. The boundary or transitional zone between adjacent communities or biomes. A tension zone (Lincoln et al. 1998).

elements. In this document, the attributes of a landscape that describe its environmental characteristics. Examples include climate, bedrock geology, surficial geology, soils, and potential vegetation.

evaluation. The comparison of dynamic sampling results to management objectives consisting of predetermined standards, expected norms, threshold values, and/or trigger points.

existing vegetation. (1) The plant cover, or floristic composition and vegetation structure, occurring at a given location at the current time. (2) The plant species existing at a location at the present time. Contrast with potential natural vegetation.

Federal Geographic Data Committee (FGDC). An interagency committee, organized in 1990 under the Office of Management and Budget Circular A-16, that promotes the coordinated use, sharing, and dissemination of geospatial data on a national basis. The FGDC is composed of representatives from 17 Cabinet level and independent Federal Agencies (FGDC 1998).

fidelity. The degree of restriction of a plant species to a particular situation, community, or association (Lincoln et al. 1998).

flora. (1) All the plant species that make up the vegetation of a given area (Allaby 1994). (2) The plant life of a given region, habitat, or geological stratum (Lincoln et al. 1998).

floristic composition. A list of plant species of a given area, habitat, or association (Lincoln et al. 1998).

forbs. Broad-leaved herbaceous plants (FGDC 1997).

fuzzy logic. A type of reasoning designed to accommodate ambiguity. Using fuzzy sets in accuracy assessment permits explicit recognition of the possibility of ambiguity regarding appropriate map labels for some locations on a map/classification. This recognition can help the user determine the relative (not absolute) accuracy of a particular classification, and thus the usefulness of that classification for applications requiring varying levels of accuracy (Wirth et al. 1996).

Geographic Information System (GIS). A set of computer tools for collecting, storing, retrieving, transforming, and displaying spatial data from the real world for a particular set of purposes. Spatial data in GIS are characterized by their position, attributes, and spatial interrelationships (topology) (Burrough 1986).

geomorphology. The classification, description, nature, origin, and development of present landforms and their relationships to underlying structures, and of the history of geologic changes as recorded by these surface features.

geospatial data. Information that identifies the geographic location and characteristics of natural or constructed features and boundaries on the Earth. This information may be derived from, among other things, remote sensing, mapping, and surveying technologies (FGDC 1998).

Global Positioning System (GPS). An array of space satellites and ground receivers that use geometry to provide information about the precise latitude, longitude, and elevation of a particular point (Wirth et al. 1996).

grid. A rectilinear arrangement. Examples include the Public Land Survey, raster GIS, and systematic field sampling schemes.

group. An aggregation of similar items. The word can also have specific meanings that vary with discipline (e.g., soil Great Groups and National Vegetation Classification System vegetation groups are very different entities).

image processing. A general term referring to manipulation of digital image data. Processing includes image enhancement, image classification, and image preprocessing (or rectification) operations (Wirth et al. 1996).

indicator species. (1) A species whose presence, abundance, or vigor is considered to indicate certain environmental conditions (Gabriel and Talbot 1984, as cited in Jennings et al. 2004). (2) A species that is sensitive to important environmental features of a site such that its constancy or abundance reflects significant changes in environmental factors. (3) A plant whose presence indicates specific site conditions or a type.

inventory. The systematic acquisition, analysis, and organization of resource information needed for planning and implementing land management (USDA NRCS 1997).

Landsat. Name for the series of Earth-observing satellites first launched in 1972 by National Aeronautics and Space Administration (originally named ERTS, for Earth Resource Technology Satellite). Landsat satellites serve as platforms for several sensors, including the return beam vidicon, Landsat Multispectral Scanner, and Landsat Thematic Mapper (Wirth et al. 1996).

landtype association (LTA). Landscape scale map units defined by a dominant geomorphic process type, similar landforms, surficial and near-surface geologic formations, and associations of soil families and potential natural vegetation at the series level (Forman and Godron 1986, ECOMAP 1993, Cleland et al. 1997).

layer (GIS). A digital information storage unit, also known as a theme. Different kinds of information (e.g., roads, boundaries, lakes, and vegetation) can be grouped and stored as separate digital layers or themes in GIS (Wirth et al. 1996).

layer or stratum. (1) A structural component of a community consisting of plants of approximately the same height structure (e.g., tree, shrub, and herbaceous layers). (2) The definition and measurement of these structural components in their vertical and height relationships to each other (e.g., tree subcanopy layer, shrub understory layer) (Grossman et al. 1998).

life form. (1) The characteristic structural features and method of perennation of a plant species; the result of the interaction of all life processes, both genetic and environmental (Lincoln et al. 1998). Life form is related to growth form, physiognomy, and habit, but also includes consideration of the type and position of renewal (perennating) buds that the other terms typically do not include. (2) Includes gross morphology (size, woodiness, etc.), leaf morphology, life span, and phenological (or life cycle) phenomena (Barbour et al. 1980).

map. (1) A spatial representation, usually graphic on a flat surface, of spatial phenomena (FGDC 1998). (2) A representation, usually on a plane surface, of a region of the Earth or heavens (Robinson et al. 1978).

mapping. In its most generic sense, the process of using points, lines, polygons, or pixels to represent geographic features spatially.

map scale. The extent of reduction required to display a portion of the Earth's surface on a map and is defined as a ratio of distances between corresponding points on the map and on the ground (Robinson et al. 1978). Scale indirectly determines the information content and size of the area being represented. The mapping scale is determined by the agency's business needs and the characteristics of the data obtained for the project area. Maps generated from digital imagery can appropriately be displayed at a range of scales.

map unit. A collection of features defined and named the same in terms of a unifying theme (USDA NRCS 1993). Each map unit differs in some respect from all others within a geographic extent. Map units are differentiated in map unit design and defined in a map unit description. Design of map units generalizes the taxonomic units present to the smallest set that meets the objectives of the map at that scale, and that are feasible to delineate with available resources and technology.

map unit characterization. The description of the elements in a map unit. In regard to ecological units, includes the “primary five” (geomorphology, geology, climate, soils, and potential vegetation), but also often includes supporting elements, such as hydrology, disturbance regimes, etc.

map unit delineation. The criteria used to spatially differentiate between map units. For ecological units, the relative importance of these criteria varies with scale. For example, at landtype association scale, differences in geomorphology and geology are normally the primary delineation criteria between map units, whereas at land unit scale, soils and potential vegetation become more important.

map unit description (MUD). Describes the composition of ecological types (or components) as they occur in a map unit. These descriptions form the primary reference document for identifying the ecological types that occur within a map unit.

map unit design. The process establishing the relationship between classifications and map products depicting them. In this document, design considerations include the interrelationships between elements, component relationships within the map unit, and how the map unit relates to other scales.

map unit legend. A list of the map units that occur in a specific inventory area, including the map unit code and map unit name, and is developed using national coding and naming procedures.

map unit validation. In this paper, the process of verifying the accuracy of ecological unit differentiation, delineation, and characterization.

metadata. Data about the data: the content, quality, condition, and other characteristics of a given set of data. Metadata is intended to provide a capability for organizing and maintaining an institution’s investment in data as well as to provide information for the application and interpretation of data received through a transfer from an external source (Jennings, et al. 2004, as modified from FGDC 1997). Metadata often includes details on the methodologies used in data collection, relevant literature references, purpose of data collection, etc.

modeling. In reference to geospatial data, the process of creating a new GIS layer by combining or operating on existing layers. Modeling creates an image (or images) that contains several types of information comprised of several GIS variables (e.g., a scene could be considered in terms of its vegetation, elevation, water, and climate at the same time) (Wirth et al. 1996).

monitoring. (1) The systematic collection, analysis, and interpretation of resource data to evaluate progress toward meeting management objectives (SRM 1998). (2) The collection and analysis of resource data to measure changes in the amounts, spatial distribution, or condition of resource types or parameters over time.

morphometry. The measurement and mathematical analysis of the configuration of the Earth’s surface and of the shape and dimensions of its landforms (i.e., relief, elevation range, slope aspect, gradient, shape, and position, dissection frequency and depth, and drainage pattern and density).

National Hierarchy of Ecological Units. The Forest Service's multiple-scale, multiple-element system of map units used to characterize the natural world and provide a framework for national forest planning and management (Cleland et al. 1997). Other State and Federal agencies also use the National Hierarchy, particularly at broader scales.

outlier. Referring to data, a sample or datum that has low similarity to all the other samples in the dataset.

overstory. The canopy layer of a forest.

patch. A relatively homogenous nonlinear area that differs from its surroundings (Forman 1995). It can specifically describe forested patches, nonforest vegetation patches, rock/barren patches, or water patches.

patterns. Repeating coordinated species abundances and groups of samples with similar species composition.

physiognomy. (1) The characteristic feature or appearance of a plant community or vegetation (Lincoln et al. 1998). (2) The overall appearance of a kind of vegetation (Daubenmire 1968, Barbour et al. 1980). (3) The expression of the life forms of the dominant plants and vegetation structure (Mueller-Dombois and Ellenberg 1974, Barbour et al. 1980).

pixel. Two-dimensional picture element that is the smallest nondivisible element of a digital (raster) image (FGDC 1998). Common pixel resolutions are 30 m and 90 m (i.e., each pixel represents a square of the Earth's surface 30 m or 90 m on a side).

plant association. A recurring potential natural plant community with a characteristic range in species composition, specific diagnostic species, and a defined range in habitat conditions and physiognomy or structure (Jennings et al. 2004). These occur as repeatable patterns across the landscape (FGDC 1997).

plot. (1) A circumscribed sampling area for vegetation (Lincoln et al. 1998). (2) Any two-dimensional sample area of any size, including quadrates, rectangular plots, circular plots, and belt-transects (which are merely very long rectangular plots). Belt-transects are often simply called strips or transects (Mueller-Dombois and Ellenburg 1974).

point. In reference to geospatial data, a dimensional-dimensional object that specifies geometric location. One coordinate pair or triplet specifies the location. Area point, entity point, and label point are special implementations of the general case (FGDC 1998).

polygon. An areal feature that occupies a unique spatial location.

potential natural vegetation (PNV). The plant community that would become established if all successional sequences were completed without human interference under the present environmental and floristic conditions, including those created by man (Tüxen 1956, as cited in Mueller-Dombois and Ellenberg 1974).

reflectance. The total solar energy incident on a given feature minus the energy that is either absorbed or transmitted by the feature. Reflectance is dependent on the material type and condition, and allows different features in a visual image to be distinguished (Wirth et al. 1996).

representative sampling. Employs systematic or random location of plots within strata, but rejection criteria may be necessary to avoid sampling obvious ecotones, which are of limited use for classifying vegetation. The gradsect technique or gradient-directed sampling is one example of this approach (Austin and Heylingers 1991, as cited in Jennings et al. 2004). It is a form of stratified random sampling that may be cost effective for sampling vegetation patterns along environmental gradients (Gillison and Brewer 1985).

resolution. The minimum difference between two independently measured or computed values that can be distinguished by the measurement or analytical method being considered or used (FGDC 1998).

remote sensing. (1) The gathering of data regarding an object or phenomenon by a recording device (sensor) that is not in physical contact with the object or phenomenon under observation (Wirth et al. 1996). (2) The science and art of obtaining information about an object, area, or phenomenon through the analysis of data acquired by device that is not in contact with the object, area, or phenomenon under investigation (Lillesand and Kiefer 1994).

scale. (1) The relationship between a distance on a map and the corresponding distance on the Earth. (2) In general, the degree of resolution at which ecological processes, structures, and changes across space and time are observed and measured (ECOMAP 1993). (3) Describes the proportion that defines the relationship of a map, image, or photograph to that which it represents, such as distance on the ground (Burrough 1986).

sensor. A device that records electromagnetic radiation or other data about an object and presents it in a form suitable for obtaining information about the environment (Wirth et al. 1996).

series. (1) In vegetation classification, an aggregation of taxonomically related plant associations that takes the name of climax species that dominate the principle layer. It is a group of associations or habitat types with the same dominant climax species. Conceptually it is analogous to an alliance, with the series being a potential natural vegetation concept (Driscoll et al. 1984). (2) In soil science, a group of soils having horizons similar in differentiating characteristics and arrangement in the soil profile, except for texture of the surface horizon (USDA NRCS 1993).

shrubs. Woody plants that generally exhibit several erect, spreading, or prostrate stems, and have a bushy appearance. In instances where life form cannot be determined, woody plants less than 5 meters in height will be considered shrubs (FGDC 1997).

site. An area delimited by fairly uniform climatic and soil conditions (similar to habitat).

spatial data. Data that record the geographic location and shape of geographic features and their spatial relationships to other features (FGDC 1998).

spatial resolution. The measure of sharpness or fineness in spatial detail. It determines the smallest object that can be resolved by a given sensor, or the area on the ground represented by each pixel. For digital imagery, spatial resolution corresponds to pixel size and may be understood as roughly analogous to “grain” in photographic images (Helms 1998).

species. In biological classification, the category below genus and above the level of subspecies and variety. It is the basic unit of biological classification (Lincoln et al. 1998).

stand. A community, particularly of trees, possessing sufficient uniformity as regards to composition, age, spatial arrangement, or condition, to be distinguishable from adjacent communities, so forming a silvicultural or management entity (Ford-Robertson 1971).

stratum. In general, one of a series of layers, levels, or gradations in an ordered system. In the natural environment, the term is used in the sense of (1) a region of sea, atmosphere, or geology that is distinguished by natural or arbitrary limits or (2) a layer of vegetation, usually of the same or similar height (FGDC 1998).

structure. (1) The spatial arrangement of the components of vegetation (Lincoln et al. 1998). (2) A function of plant size and height, vertical stratification into layers, and horizontal spacing of plants. Physiognomy refers to the general appearance of the vegetation, while structure describes the spatial arrangement of plants in more detail. Physiognomy should not be confused with structure (Mueller-Dombois and Ellenberg 1974).

succession. Partial or complete replacement of one community by another (Daubenmire 1978).

surficial geology. The mode of deposition of unconsolidated deposits lying on bedrock or occurring on the Earth’s surface, and the rock type(s) from which those deposits are derived, known as “kind” and “origin,” respectively.

taxa. The plural form of taxon, which is a classification entity.

taxonomic unit. The basic set of classes or types that comprise a classification; in this document, a classification of environmental elements or integrated environmental elements (ecological types). Taxonomic units represent a conceptual description of ranges and/or modal conditions in environmental characteristics. A taxonomic unit (or taxon) is a class developed through the scientific classification process, or a class that is part of a taxonomy (USDA NRCS 1993). A taxonomic unit is the physical representation of a taxon, or the physical representation of a unit of a classification.

theme. (1) A group of data that represent a place or thing such as soils, vegetation, or roads. A theme could be less concrete such as population density, school districts, or administrative boundaries (FGDC 1998). (2) For a GIS context, see **layer**.

trees. Woody plants that generally have a single main stem and have more or less definite crowns. In instances where life form cannot be determined, woody plants equal to or greater than 5 meters in height will be considered trees (FGDC 1997).

user's accuracy. In reference to accuracy assessment, an accuracy measure based on a commission error as shown in the error matrix. Also known as reliability, user's accuracy is the probability that pixels classified on the map actually represent the category on the ground. User's accuracy is calculated by dividing the total number of correctly classified sites of a certain category by the total number of the certain category classified by the map (Wirth et al. 1996).

vascular plant. Plant with water and fluid conductive tissue (xylem and phloem), including seed plants, ferns, and fern allies (FGDC 1997).

vegetation cover. Vegetation that covers or is visible at or above the land or water surface. It is a subcategory of Earth cover. The percentage of the ground covered by a vertical projection of the outermost perimeter of the natural spread of the foliage of plants (FGDC 1997).

vegetation data. The attributes of the vegetation that are used to classify and characterize the vegetation type and to map vegetation stand. These data come from the interpretation of remotely sensed imagery, fieldwork, and other thematic data sources (FGDC 1997).

vegetation mapping. The process of delineating the geographic distribution, extent, and landscape patterns of vegetation types based on composition, physiognomy, and structure.

vegetation type. A named class of plant community or vegetation defined on the basis of selected shared floristic, physiognomic, and/or structural characteristics, which distinguish it from other classes of plant communities or vegetation (Jennings et al. 2004).

Appendix C. Vegetation Ocular Forms and Codes

This appendix includes examples of forms for recording plot metadata, environmental attributes, and vegetation data for ocular macroplots which provides a minimum set of vegetation data required for Terrestrial Ecological Unity Inventory (TEUI).

Plot Location

Locate the plot within a representative and uniform portion of the vegetation and site conditions to be sampled. The plot should not cross-obvious ecotones of vegetation or site conditions. In some cases, you may locate the plot to sample vegetation and site conditions within broad ecotones.

Mark the center of the plot, measure, and flag the outside edge. Place flagging or metal pins upslope, downslope, and along the contour to the left and right of plot center. Once you mark the plot boundary, walk around the plot and become familiar with the plant species, ground cover, vegetation layering, and other ecological characteristics.

Calibration

Conduct ocular estimate calibration at the beginning of inventory projects and periodically throughout the life of the project. Calibrate ocular estimates by using cover frequency and/or line intercept transect methods (refer to *National Range Protocols* [USDA Forest Service 2003c] for these methods). Examiners usually calibrate their ocular estimates by periodically double sampling with cover frequency transects. Minimal variability usually exists between trained examiners on canopy cover estimates and is negated by the many samples that can be obtained with this method.

Cover Frequency

The cover frequency method uses a 20 cm x 50 cm Daubenmire frame systematically placed along a transect to record quantitative values for canopy cover and ground cover. Species composition is then determined from canopy cover, frequency, and ground cover. The cover frequency method is best for vegetation types of less than 1 meter in height. Specific methods for conducting cover frequency are identified in the *National Range Protocol's* "Cover Frequency Field Guide" (USDA Forest Service 2003a). Note: While the protocol requires a minimum of 3 transects and 60 frames, we recommend a total of only 30 frames.

Line Intercept

The line intercept method consists of a line transect, usually in multiples of 100 feet, where measurements are made of the crown spread of the various plants that are bisected by the transect line. The line intercept method is commonly used for measurement of semi-arid shrub and bunchgrass vegetation types. Specific methods for conducting line intercept sampling method are identified in the *National Range Protocol's* "Line Intercept Field Guide" (USDA Forest Service 2003b).

Absolute numbers facilitate the ease of data sharing, can be easily converted to cover classes, and, in the case of classes with wide ranges at the lower end, may increase accuracy in analysis. Absolute percent cover of the fixed area plot is the standard and is required. Cover classes are optional and are accommodated in the Natural Resource Information System (NRIS) Terra database. Class code sets will be stewarded by regions.

Species Identification

Vascular Species

Integrated plots require a list of all vascular species and their percent canopy cover. Lichens/nonvascular species are optional. Species should be organized on the field form by life form class. Use taxonomy supported by locally/regionally accepted floras. Identify to species level. In identifying subspecies/variety level, default to local/regional direction. (The NRIS Terra data form will display all four levels of scientific name when plant code is entered.) Natural Resources Conservation Service (NRCS) PLANTS database symbols (plant code) are the standard national coding system for plants. All codes in the NRCS PLANTS database are valid choices.

Coding and Collection of Unknown Species

Immature plants that cannot be identified to the species level should be identified to the genus level. The NRCS PLANTS database has symbols for the genus level when species cannot be determined. When species or genus cannot be determined, use the most appropriate general organism code for an unknown plant. Mature plants that cannot be identified in the field should be collected and pressed for later identification. Assign a collection number to the collection and record on a data line on the field form along with other required information (percent cover, etc.). For unknown species and/or species collected for subsequent identification, use an appropriate NRCS general organism code for the plant symbol (e.g., 2FORB = unknown forb). See the National PLANTS database (<http://plants.usda.gov>) for a complete list of these codes.

Collection Numbers

Assign collection numbers that enable pressed samples to be easily related back to field forms or database entries later. At a minimum, record collection number, examiner, and date on the collection. For example, label the collected plant with the site ID followed by a unique number for the plant collected on that plot. The collection number identifies that plant on the field form. For example, if three unknown plants were collected on plot 642, they could be recorded as 642-1, 642-2, and 642-3. It is not necessary to re-collect the same unknown species on every plot. If the same unknown species obviously is present on additional plots, that same collection number could be referenced on the field form for that plot. For example, if two unknown species occurred on plot 645, one a “new” discovery and the other collected previously on plot 642, they could be recorded as 645-1 (the new unknown) and 642-3 (the collection number assigned to a previously collected plant).

Legacy Plant Coding Systems

NRCS PLANTS database symbols (plant codes) are the required standard national coding system for plants. While the maintenance and continued use of local or “legacy” plant coding systems (such as Regional code sets) is discouraged, such codes still may have utility in working with non-Forest Service partners and with legacy data sets/publications. The NRIS Terra database accommodates legacy-coding systems by supporting a crosswalk table between legacy systems and the NRCS PLANTS database that is managed by the Regional Plants database steward. Coordinate with your Regional Plants database steward for access to legacy coding systems.

Productivity

Numerous methods can estimate the productivity potential for an ecological type or map unit component. TEUI projects should provide at least one measure of site productivity. Examples of productivity measures include site index, growth basal area, potential productivity, stand density index, and growth estimates.

Site index is a measure of site productivity expressed by the height-to-age relationship of dominant and co-dominant trees of a given species at a given base age. It is an index of site yield capability.

Growth basal area is an index of forest stand stockability (Hall 2003) It uses the relationship between current radial increment or dominant trees, current total stand basal area, and age to index the capability of a site to support and grow wood volume.

Potential productivity can be determined for rangelands by clipping and weighing vegetation, which is often done by either species or life form. Clipping by species should be done when characterizing ecological sites and correlating with NRCS.

Stand density-index based volume index is an index of yield capacity that uses spatial data interference adjustments to normal yield tables.

C.1 Instructions for General Site Data Form

Collect the following data elements at all sample sites: R=Required, O=Optional.

Field Name	Instructions
Site ID	R Record a plot number or site identifier that is unique within the project.
Project Name	R Record the name of the project.
Date	R Record the month, day, and year in the format MM-DD-YYYY.
Sample Type(s)	R Record the type(s) of data collected on the plot using the following codes: OCMA = Ocular macroplot FLLI = Flora line intercept FLCO = Flora cover/frequency FLPO = Flora point cover FLTR = Flora tree data SOPE = Soil pedon (individual tree measurements)
Examiner(s)	R Record the last name, first name, and middle initial of all crewmembers. Record the name of the principal investigator first.
Plot Location Type	R Record the approach used to locate the plot using the following codes: P = Preferential R = Random S = Stratified random (or systematic) See section C.2.3 for a discussion of sampling strategies.
Species List Type	R Record the completeness of the plant species list for the plot using the following codes: C = Complete. All plant species present at time of sampling are recorded. R = Reduced. Not all plant species are recorded. The list may be limited by a cover threshold (e.g. > 5% cover) or relative abundance (e.g., five most abundant species). S = Selected. Not all plant species recorded. A protocol- or project-specific list of species are recorded whenever they are present on a plot. L = Life form only. No species are recorded. Cover is only recorded for life forms, and usually by layer or size class within life form. A complete species list is required for developing and describing new associations and alliances. See section C.2.4.3 for more information.
Plot Area	R Record the area of the macroplot or belt-transect in either acres or square meters, and the unit of measure (UOM) used. See section C.2.4.1 for guidelines for determining plot size.
Plot Size	R Record actual plot dimensions, using radius for circular plots, and width and length for rectangular plots. Also record the UOM used.

Field Name	Instructions
Vegetation Classification	R Record as much classification information as known at the time of sampling including the potential natural vegetation (PNV) series, association, and reference; existing vegetation alliance, association, and reference; ecological type; and Federal Geographic Data Committee (FGDC) subclass. Subclass is determined in the field using the key in appendix 1C of the <i>Existing Vegetation Classification and Mapping Technical Guide</i> (Brohman and Bryant, eds. 2005).
GPS Location	R Record the location of the sample site using latitude-longitude or Universal Transverse Mercator with zone.

Field Name	Instructions
Aerial Photo ID	O Record the photo identification number.
Flight Line	O Record the three-digit photo flight line.
Roll #	O Record the three-digit roll number and contract fiscal year. For example, “189” identifies roll 1 taken in fiscal year 1989.
Plot Photo Label	O Record a descriptive alpha/numeric label to track photos. For example, roll number followed by exposure # “2-14” to help label and track photos after processing.
Photo Description	O Record a description of the photo subject.
Film Type	O Record the type of film when a film camera is used.
Digital Photo File Name	O Record the filename of the photo when a digital camera is used.
Elevation	R Record the sample site elevation, in feet, to the nearest 10 feet.
Slope	R Record the sample site average slope, in percent.
Aspect	R Record the sample site aspect, in degrees. For slopes that have no aspect, record a zero. For due north, record 360.
Horizontal Slope Shape	O Record the horizontal shape of the plot. See section C.1.1 and figure C.1 for values and codes.
Vertical Slope Shape	O Record the vertical shape of the plot. See section C.1.1 and figure C.1 for values and codes.
Slope Complexity	O Record the slope complexity of the plot using the following codes: S = Simple. Linear, convex, or concave in shape. C = Complex. Broken, undulating, or patterned in shape.
Slope Position	R Record the two-dimensional position of the plot on the landform using the following codes: SU = Summit SH = Shoulder BS = Backslope FS = Foothill TS = Toeslope
Slope Position Modifier	R Record the modifier which best describes the primary slope position using the following codes: LR = Lower MD = Mid UP = Upper
Ground Surface Cover Type	R Record each ground surface cover type present in the plot. See sections C.1.2 and C.1.3 for types, descriptions, and codes.
Ground Surface Cover Percent	R Record an ocular estimate of the percentage of the plot covered by each ground surface cover type.

Field Name	Instructions
Disturbance Type	O Record major disturbance events. See Section C.1.4 for a list of disturbance types and codes.
Disturbance Extent Affected	O Record the vegetation affected and/or the ground cover affected, in percent.
Disturbance Date	O Record the disturbance date, in years, to the nearest year.
Disturbance Notes	O Record notes relating to major disturbance event. Include the type of vegetation or species affected.

C.1.1 Vertical and Horizontal Shape Code

The following codes should be used for vertical and horizontal slope shape:

Code	Description
BR	Broken. Cliffs, knobs, and/or benches interspersed with steeper slopes; generally characterized by sharp, irregular breaks.
CV	Convex. Raised, arched up, curved out.
LI	Linear/Planar. Straight, even, or smooth.
CC	Concave. Depressional, curved in.
UN	Undulating (also rolling). Pattern of one or more low relief ridges or knolls and draws
PA	Patterned. Relief of hummocks and swales with several feet
FL	Flat. Straight and level.
XX	Unable to assess.

Figure C.1. *Vertical and horizontal slopes*

C.1.2 Ground Surface Cover

Ground surface cover estimates are ocular. Absolute percent cover of the fixed area plot is the standard and required. Ground surface cover is defined as the percentage of plot surface area that is occupied by the ground cover type. Estimate to the nearest 1 percent

in the 1 to 10 percent range, to the nearest 5 percent for amounts exceeding 10 percent. Figure C.2 illustrates some ground cover types. The following reduced set of ground cover categories is used in existing vegetation classification to describe and develop interpretations for ground cover and document disturbance effects:

Code	Description
BARE	Bare soil. Soil particles < 2 mm not covered by rock, cryptogams, or organic material. Does not include any part of a road, but does include foot trails.
Live Vegetation Categories	
BAVE	Basal vegetation. Basal vegetation is the soil surface occupied by live basal or root crown portion of vascular plants, including live trees. Typically ranges between 3 and 7%; 15% is very high and rarely encountered.
NONV	Nonvascular. Plants or plant-like organisms without specialized water or fluid conductive tissue (xylem and phloem). Includes mosses, liverworts, hornworts, lichens, algae, and bacterial soil crusts.
Organic Debris Categories	
LITT	Litter. Plant litter and duff not yet incorporated into the decomposed top humus layer. Includes twigs < 1/4 inch in diameter, ash from burned plants, dead nonvascular plants, and dung.
WOOD	Wood. Any dead woody material > 1/4 inch in diameter, small and large woody debris, regardless of depth. Includes bases of standing dead trees and shrubs.
Rock Categories	
BEDR	Bedrock. A general term for the rock, usually solid, that underlies soil or other unconsolidated, superficial material.
BOUL	Boulders. Rock > 600 mm (24 inches) in diameter or length.
COBB	Cobbles. Rock fragments between 75 and 250 mm (3 and 10 inches) in diameter.
GRAV	Gravel. Rock fragments between 2 and 75 mm in diameter.
PAVE	Pavement. A natural concentration of closely packed and polished stones at the soil surface in a desert (may or may not be an erosional lag). Also, rock fragments < 19.1mm in diameter.
ROCK	Total rock. Relatively hard, naturally formed mineral or petrified matter > 2mm in diameter.
RROC	Range rock. Rock fragments > 3/4 inch (19.1 mm) in diameter.
STON	Stones. Rock fragments between 250 and 600 mm (10 and 24 inches) in diameter.
Miscellaneous Categories	
PEIS	Permanent ice and snow. Surface area covered by apparently permanent ice and/or snow at the time of plot measurement.
ROAD	Road. Any road or vehicle trail that is regularly maintained or in long-term continuous use. Includes cutbanks and fills.
TRIS	Transient ice and snow. Surface area covered by apparently transient ice and/or snow at the time of plot measurement.
WATE	Water. Includes transient water that obscures other cover types and permanent water where the water table is above the ground bogs, swamps, marshes, and ponds.

Figure C.2. *Ground surface cover types*

The following ground cover types should be recorded whenever present and are included on the example General Site Data form: bare soil, basal vegetation, nonvascular, litter, and wood. More detailed subdivisions of these categories are available in the NRIS Terra database, but are not recommended for vegetation classification. The miscellaneous categories should also be recorded whenever present. Rock cover must be recorded using one of the three sets of categories described below.

C.1.3 Rock Ground Cover Types

Rock cover on the ground surface should be described using one of the following sets of ground cover types. Set 1 is the minimum requirement. Set 2 is used primarily for specific rangeland monitoring methods. Set 3 is recommended for vegetation classification and description done in conjunction with TEUI.

Rock Set 1		Rock Set 2		Rock Set 3	
ROCK	All rock from gravel to bedrock.	PAVE	Pavement (2–19.1 mm diam.)	GRAV	Gravel (2–75 mm diam.)
		PROC	Rock (> 19.1 mm diam.)	COBB	Cobbles (75–250 mm diam.)
				STON	Stones (250–600 mm diam.)
				BOUL	Boulders (> 600 mm diam.)
				BEDR	Bedrock

C.1.4 Disturbance Event Code Categories

The following codes should be used for disturbance and treatment types:

Code	Disturbance or Treatment	Code	Disturbance or Treatment
10000	Insects (general)	50003	Drought
10011	Ant (Formicidae)	50004	Flooding/high water
11000	Bark beetles	50011	Snow/ice
12000	Defoliators	50013	Wind/tornado
13000	Chewing insects	50015	Avalanche
14000	Sucking insects	50016	Mud/landslide
15000	Boring insects	51001	Channel erosion
16000	Seed/cone/flower/fruit insects	51002	Soil creep
17000	Gallmaker insects	51010	Slump
18000	Insect predators	70005	Land clearing
19000	General diseases	70006	Land use conversion
20000	Biotic damage	70008	Mechanical
21000	Root/butt diseases	71000	Timber harvest
22000	Stem decay/cankers	71002	Firewood harvest
23000	Parasitic/epiphytic plants	71027	Natural changes (no cut)
23001	Mistletoe	73000	Regeneration activities (general)
24000	Decline complexes/dieback/wilts	73004	Seeding (trees-natural)
25000	Foliage diseases	73005	Seeding (trees-artificial)
26000	Stem rusts	73008	Grass seeding
27000	Broom rusts	73015	Site preparation
30000	Fire	73016	Brush control
41002	Beaver	74000	Timber stand improvement (general/noncommercial)
41003	Big game (e.g., deer)	75000	Prescribe burning (general)
41016	Browsing	75004	Planned ignition/prescribed burn/natural fuels
41021	Rodents	75005	Unplanned ignition/prescribed burn/natural fuels
41022	Elk	78007	Miscellaneous upland recreation activities
42001	Cattle	78008	Miscellaneous riparian recreation activities
42004	Sheep	80000	Multi-damage (insects/diseases)
		90000	Unknown

C.2 Instructions for Vegetation Composition Form

The Vegetation Composition Form can be used to record or summarize data for a number of sampling methods. Its use for the ocular macroplot method is described here.

C.2.1 Vegetation Sampling Metadata

The first part of the Vegetation Composition Form records metadata about the vegetation sampling methods and who collected the data. The plot location should be recorded on the General Site Data Form.

Field Name		Instructions
Site ID	R	Record a plot number or site identifier that is unique within the project. This must match the Site ID on the General Site Data Form.
Date	R	Record the month, day, and year in the format MM-DD-YYYY.
Examiner(s)	R	Record the last name, first name, and middle initial of all crewmembers. Record the name of the principal investigator first.
Sample Type	R	Record the type of data collected on the plot using one of the following codes: OCMA = Ocular macroplot FLLI = Flora line intercept FLCO = Flora cover/frequency FLPO = Flora point cover FLTR = Flora tree data
Species List Type	R	Record the completeness of the plant species list for the plot using the following codes: C = Complete. All plant species present at time of sampling are recorded. R = Reduced. Not all plant species are recorded. The list may be limited by a cover threshold (e.g., > 5% cover) or relative abundance (e.g., five most abundant species). S = Selected. Not all plant species recorded. A protocol- or project-specific list of species are recorded whenever they are present on a plot. L = Life form only. No species are recorded. Cover is only recorded for life forms, and usually by layer or size class within life form. A complete species list is required for developing and describing new associations and alliances. See section C.2.4.3 for more information.
Plot Area	R	Record the area of the macroplot or belt transect in either acres or square meters, and the UOM used. See section C.2.4.1 for guidelines for determining plot size.
Area UOM	R	Record the UOM for the plot area, either acres or square meters.
Plot Size	R	Record actual plot dimensions, using radius for circular plots, and width and length for rectangular plots. Also record the UOM used.
Size UOM	R	Record the UOM for the plot dimensions, either feet or meters.
Height UOM	R	Record the UOM for plant heights, either feet or meters.
Diameter UOM	R	Record the UOM for tree diameters.

C.2.2 Canopy Cover by Life Form

Record the canopy cover for each item in this part of the form. Canopy cover is “the percentage of ground covered by a vertical projection of the outermost perimeter of the natural spread of foliage of plants. Small openings within the canopy are included” (SRM 1998, USDA NRCS 1997). See sections 2.2.3.3 and 2.4.5 of the *Existing Vegetation Classification and Mapping Technical Guide* (Brohman and Bryant, eds. 2005) for more information about canopy cover and ocular estimation techniques.

Complete the fields in this part of the form as follows:

All vegetation	Total vegetation cover. Record the percentage of the ground covered by a vertical projection of the outermost perimeter of the natural spread of foliage of all vascular plants within the sample unit (plot or transect).
Trees	Tree cover. Record the total cover of trees, defined as woody plants that generally have a single main stem, have more or less definite crowns, and are usually equal to or greater than 5 meters in height at maturity (see section 2.4.2.1 of Brohman and Bryant 2005).
Shrubs	Shrub cover. Record the total cover of shrubs, defined as woody plants that generally have several erect, spreading, or prostrate stems which give it a bushy appearance, and are usually less than 5 meters in height at maturity (see section 2.4.2.1 of Brohman and Bryant 2005). Shrub cover includes the cover of dwarf shrubs.
Dwarf shrubs	Dwarf shrub cover. Record the total cover of dwarf shrubs, defined as caespitose, suffrutescent, matted, or cushion-forming shrubs which are typically less than 50 cm tall at maturity due to genetic and/or environmental constraints (see section 2.4.2.1 of Brohman and Bryant 2005).
Herbs	Herb cover. Record the total cover of herbs, defined as vascular plants without significant woody tissue above the ground, with perennating buds borne at or below the ground surface (see section 2.4.2.1 of Brohman and Bryant 2005). Includes forbs, graminoids, ferns, and fern allies. Herb cover must be equal to or less than the sum of graminoid cover and forb cover.
Graminoids	Graminoid Cover. Record the total cover of graminoids, defined as flowering herbs with relatively long narrow leaves and inconspicuous flowers with parts reduced to bracts. Include grasses, sedges, rushes, and arrowgrasses (see section 2.4.2.1 of Brohman and Bryant 2005).
Forbs	Forb Cover: Record the total cover of forbs, defined as spore-bearing herbs or flowering herbs with relatively broad leaves and/or showy flowers (see section 2.4.2.1 of Brohman and Bryant 2005). Include ferns or fern allies.

Dwarf shrubs are a subcategory of shrubs. Forbs, graminoids, and fern-like are subcategories of herbs. Total canopy cover of additional life forms can be recorded in part 3 of the Vegetation Composition Form as needed.

C.2.3 Canopy Cover by Species

The third part of the Vegetation Composition Form is used to record data about vegetation layers and individual plant species. This portion of the form is divided into a section for trees and shrubs and a section for herbs and nonvascular organisms.

Record a complete list of all plant species within the sampling unit. Record only those species present in the plot. Do not record species that are present in the stand but do not occur within the plot. Record the canopy cover for each species. Do not use cover classes. Estimate percent canopy cover of each species, life form, layer, or size class within the plot as follows:

- Use 0.1 as “trace” for items present but clearly less than 1 percent cover.
- Estimate to the nearest 1 percent between 1 and 10 percent cover.
- Estimate to at least the nearest 5 percent between 10 and 30 percent cover.
- Estimate to at least the nearest 10 percent for values exceeding 30 percent cover.

Record a life form and life form modifier for each species using the codes in tables 2.5 and 2.6, respectively, of the *Existing Vegetation Classification and Mapping Technical Guide* (Brohman and Bryant, eds. 2005). These codes are used for crosswalking to the FGDC physiognomic hierarchy and describing physiognomy of associations and alliances (Jennings et al. 2004).

C.2.4 Canopy Cover and Structural Data by Layer

Species data may also be recorded by layer if desired. The following instructions describe how to record data for tree and shrub layers, and for tree and shrub species by layer.

C.2.4.1 Tree Layer Definitions

Trees vary widely in mature height, from 5 meters to more than 50 meters (FGDC 1997). This variation must be taken into account when defining layers or height classes for trees. For this purpose, a dwarf tree is defined as a tree that is typically less than 12 meters tall at maturity due to genetic and/or environmental constraints. A stand of dwarf trees typically has a site-specific potential height growth of less than 12 meters. The layers described below are defined separately for dwarf trees where necessary.

The following tree layers must be described whenever they are present in the sampling unit (e.g., macroplot or transect):

Overstory (TO) The overstory layer includes all trees greater than or equal to 5 meters in height that make up the forest canopy. In dwarf tree stands, the

overstory consists of trees that have attained at least half of their site-specific potential height growth and make up the forest canopy.

Regeneration (TR) The regeneration layer includes all trees less than 5 meters in height. In dwarf tree stands the regeneration layer includes trees that have attained less than half of their site-specific potential height growth and are clearly overtopped by the overstory trees.

The overstory may optionally be subdivided into the following sublayers, if they occur, to describe stand structure in more detail:

Main canopy (TOMC) The dominant and co-dominant overstory trees that receive direct sunlight from above and make up the majority of the forest canopy.

Supercanopy (TOSP) Scattered overstory trees that clearly rise above the main canopy.

Subcanopy (TOSB) Overstory trees that are clearly overtopped by and separate from the main canopy, but are larger and taller than the regeneration layer.

The regeneration layer may optionally be subdivided into the following sublayers:

Saplings (TRSA) Regenerating trees greater than 1.4 meters (4.5 feet) in height, *or* regenerating dwarf trees greater than 1 meter in height.

Seedlings (TRSE) Regenerating trees less than 1.4 meters (4.5 feet) in height, *or* regenerating dwarf trees less than 1 meter in height.

C.2.4.2 Tree Layer Data Requirements and Instructions

Canopy cover, predominant plant height, and predominant crown height must be recorded for the tree overstory and regeneration layers. Predominant diameter must also be recorded for the overstory. Record these attributes using the following procedures:

Canopy cover	Record percent canopy cover for each layer and optional sublayer occurring within the sampling unit. Canopy cover of a layer cannot be greater than the sum of the canopy cover values of its sublayers. Layer cover, however, typically is less than the sum of the sublayer covers due to overlapping of the sublayers.
Predominant plant height	Record the predominant, or prevailing, tree height for the overstory and regeneration layers to the nearest meter and nearest foot, respectively. This attribute is determined by selecting a representative tree for the layer and estimating its height using a clinometer and measuring tape. The representative tree for the overstory layer must be in the main canopy. The representative tree for the regeneration layer must be from the sublayer (sapling or seedling) with the most canopy cover. Predominant plant height may also be recorded for each optional sublayer.

Predominant crown height	Record the predominant, or prevailing, crown height for the overstory and regeneration layers to the nearest meter. Crown height is the vertical distance from ground level to the lowest whorl with live branches in at least three of four quadrants around the stem. It is determined by selecting a representative tree for the layer and estimating its crown height using a clinometer and measuring tape. The representative tree for the overstory layer must be in the main canopy. The representative tree for the regeneration layer must be from the sublayer (sapling or seedling) with the most canopy cover. Predominant crown height may also be recorded for each optional sublayer.
Predominant diameter	Record the predominant, or prevailing, tree diameter for the overstory layer to the nearest inch. Predominant diameter is the prevailing diameter of the most abundant tree species in a layer or sublayer. It is determined by selecting a representative tree and measuring it with a diameter tape, using procedures described in the <i>Common Stand Exam Field Guide</i> . The representative tree for the overstory layer must be in the main canopy. Measure the diameter at breast height (d.b.h.) whenever possible; otherwise, measure diameter at root crown (d.r.c.), and record the diameter in the appropriate column (d.b.h. or d.r.c.) of the Vegetation Composition Form.

An example of both the required and optional data for tree layers is shown below.

Required layers and data are in bold text. Heights are in meters and diameters in inches.

Table C.1. *Example of completed data for tree layers and sublayers.*

Life form	LF mod.	Layer	Species	Canopy cover	Pred. plant height	Pred. crown height	Pred. d.b.h.	Pred. d.r.c.
T	—	TO	—	45	10	6	12	—
T	—	TOSP	—	5	12	8	15	—
T	—	TOMC	—	40	10	6	12	—
T	—	TOSB	—	10	7	2.5	8	—
T	—	TR	—	10	4	0.3		
T	—	TRSA	—	5	4	0.3		
T	—	TRSE	—	5	0.3	0		

C.2.4.3 Data for Shrub Layers

The following shrub layers may optionally be described when present in the sampling unit (e.g., macroplot or transect):

Tall shrubs Shrubs greater than 2 meters in height. (May occasionally include shrubs over 5 meters tall but clearly multi-stemmed.)

Medium shrubs Shrubs 0.5 to 2 meters in height.

Low shrubs Shrubs less than 0.5 meter in height.

When shrub layers are described, canopy cover and predominant plant height should be recorded for each layer. Predominant crown height may also be recorded. Record these attributes using the following procedures:

Canopy cover	Record percent canopy cover for each shrub layer occurring within the sampling unit. Total shrub cover cannot be greater than the sum of the individual layer cover values, but may be less.
Predominant plant height	Record the predominant, or prevailing, height of each shrub layer to at least the nearest foot. Predominant plant height is the prevailing upper height of the shrubs within a layer. It is determined by selecting a representative individual shrub and measuring its height with an appropriate method (e.g. tape measure for low to medium shrubs or clinometer for tall shrubs).
Predominant crown height	Record the predominant crown height for each shrub layer to at least the nearest foot. Crown height for shrubs is the vertical distance from ground level to the lowest live foliage or branches. It is determined by selecting a representative shrub for the layer and measuring or estimating its crown height.

An example of completed shrub layer data is shown below. Heights are in meters.

Table C.2. *Example of completed data for shrub layers.*

Life form	LF mod.	Layer	Species	Canopy cover	Pred. plant height	Pred. crown height
S	—	ST	—	1	3	1
S	—	SM	—	9	1	0.3
S	—	SL	—	Tr	0.3	0

C.2.5 Optional Canopy Cover and Structural Data by Species by Layer

Canopy cover and structural data may optionally be recorded separately for each species for each layer or sublayer in which it occurs.

C.2.5.1 Data for Tree Species by Layer

Canopy cover. Record the total canopy cover of each tree species and the canopy cover of each species within each layer in which it occurs. Cover by sublayer may also be recorded, requiring up to eight rows of data, depending on the number of sublayers in which a species occurs. An example is shown in table C.3 with required data in bold text. In this example, the canopy cover of Ponderosa pine (*Pinus ponderosa*) is 45 percent. Within the overstory and regeneration layers, its canopy cover is 35 and 10 percent, respectively, indicating no overlap between the two layers. No sapling or seedling occurs directly under an overstory tree. Overlap occurs, however, between main canopy and subcanopy trees. Ponderosa pine cover is 30 percent in the main canopy and 10

percent in the subcanopy, while overstory cover is only 35 percent. This indicates 5 percent overlap between main canopy and subcanopy Ponderosa pine.

The possibility of overlap between sublayers requires that overstory and regeneration cover for each tree species be estimated or measured directly, not calculated by summing the sublayer values. When recording species cover by sublayer using the ocular macroplot method, it is most efficient to first estimate canopy cover by sublayer, then estimate the overlap (if any) between sublayers to derive canopy cover for the overstory and regeneration layers.

Table C.3. *Example of tree species by layer canopy cover data.*

Life Form	LF Mod	Layer	Species	Canopy Cover
<i>T</i>	<i>TN</i>	—	<i>PIPO</i>	45
<i>T</i>	<i>TN</i>	<i>TO</i>	<i>PIPO</i>	35
<i>T</i>	<i>TN</i>	<i>TOMC</i>	<i>PIPO</i>	30
<i>T</i>	<i>TN</i>	<i>TOSB</i>	<i>PIPO</i>	10
<i>T</i>	<i>TN</i>	<i>TR</i>	<i>PIPO</i>	10
<i>T</i>	<i>TN</i>	<i>TRSA</i>	<i>PIPO</i>	6
<i>T</i>	<i>TN</i>	<i>TRSE</i>	<i>PIPO</i>	4

Predominant plant height. Record predominant height of each tree species for each layer in which it occurs. It is determined by selecting a representative tree and estimating its height using a clinometer and measuring tape, using procedures described in the *Common Stand Exam Field Guide* (2005).

Predominant crown height. Record predominant crown height of each tree species for each layer in which it occurs. It is determined by selecting a representative tree and estimating or measuring the vertical distance from the ground to the canopy base.

Predominant age. Record the predominant age of each tree species in the overstory layer. Refer to the *Common Stand Exam Field Guide* (2005) for methods of determining tree age.

Predominant diameter. Record predominant diameter (d.b.h. or d.r.c. as appropriate) for the overstory layer. It is determined by selecting a representative tree and measuring it with a diameter tape, using procedures described in the *Common Stand Exam Field Guide* (2005).

Stem count. Record stem counts for each tree species occurring in the regeneration layer. Stems may optionally be recorded by sublayer (sapling and seedling). Counts can be made on the entire plot or on a portion of the plot depending on the density of

each species. When stems are counted on a portion of the plot, the fraction of the plot and the raw count are recorded in the remarks section of the form. These are then used to calculate a count for the entire plot, which is recorded in the stem count column of the form.

An example of a completed data set for one tree species is shown in table C.4. Predominant plant height, crown height, diameter, age, and stem count have been added

Life form	LF mod.	Layer	Species	Canopy cover	Pred plant ht.	Pred. crown height	Pred. d.b.h.	Pred. d.r.c.	Pred. age	Stem count
<i>T</i>	<i>TN</i>	—	<i>PIPO</i>	45

C.2.5.2 Data for Shrub Species by Layer

Canopy cover. Record the total canopy cover of each shrub species. The canopy cover of each species within each layer in which it occurs may be recorded optionally. This process may require up to four rows of data, depending on the number of layers in which a shrub species occurs. The possibility of overlap between layers requires that total canopy cover for each shrub species be estimated or measured directly, not calculated by summing the species by layer cover values.

Predominant crown height. Record predominant crown height of each shrub species for each layer in which it occurs. It is determined by selecting a representative shrub and estimating or measuring the vertical distance from the ground to the lowest live foliage.

Predominant height. Record predominant height of each shrub species or optionally for each layer in which the species occurs. Predominant height is the prevailing upper height of the shrub species within a layer. It is determined by selecting a representative individual shrub and measuring its height with an appropriate method (e.g., tape measure for low to medium shrubs or clinometer for tall shrubs).

An example of completed shrub species and species by layer data is shown below. Heights are in meters.

Table C.5. Example of completed data for shrub species by layers.

Life form	LF mod.	Layer	Species	Canopy cover	Pred. plant height	Pred. crown height
<i>S</i>	<i>SBD</i>	—	<i>QUGA</i>	9	1	0.2
<i>S</i>	<i>SBD</i>	<i>ST</i>	<i>QUGA</i>	1	3	1
<i>S</i>	<i>SBD</i>	<i>SM</i>	<i>QUGA</i>	8	1	0.2
<i>S</i>	<i>SM</i>	—	<i>ARTRP4</i>	1	0.7	0.2
<i>S</i>	<i>SM</i>	<i>SM</i>	<i>ARTRP4</i>	1	0.7	0.2

C.2.6 Basal Area Data

Basal area may optionally be collected using a single prism point at the center of a macroplot or midpoint of a transect. Follow the procedures in the *Common Stand Exam Field Guide* (2005). Record the basal area, in square feet per acre, and the expansion factor of the prism used.

C.2.7 Blank Vegetation Composition Form and Completed Examples

A blank Vegetation Composition Form is provided below, followed by examples of a completed General Site Data Form and Vegetation Composition Form.

NOTES										

Geology and Geomorphology Form Instructions

Field Name	Description and Action To Be Taken
Site ID	Record the identifier that is unique within a specific project or inventory area.
Date	Enter the date the site was described. Example: 7-8-97.
Examiner	Enter the name of the person(s) describing the site.

Bedrock Geology

Field Name	Description and Action To Be Taken
Sequence Number	If more than one rock type will be described at the site, number from the top down.
Primary Lithology	Select primary lithology term from the table on page 152. Example: Sedimentary.
Secondary Lithology	Select secondary lithology term from the table on page 152. Example: Sandstone.
Texture Modifier	Select term from the table on page 160. Example: Clastic.
Depth to Bedrock Class	Estimate the depth to bedrock and place in appropriate class from the table on page 152. Example: DEEP.
Weathering	Determine weathering state from the table on page 152. Example: PDS – Partially Decomposed.
Chemistry Modifier	Select appropriate term from the table on page 163. Example: AC – Acidic.
Structure Type	Select appropriate term from Appendix A. Example: BE – Bedding.
Azimuth/Inclination	Record the azimuth of the strike and inclination of the dip in degrees. Example: 200/15.
Fracture Interval	Select appropriate class from the table on page 163. Example: 1 < 10 cm between fractures.
Stratigraphy	Locally determined values for unit name and age. Example: Kbb – Blind Bull Formation.

Parent/Surficial Material

Field Name	Description and Action To Be Taken
Sequence Number	If more than one rock type will be described at the site, number from the top down.
Origin	Select either primary lithology or secondary lithology from the table on page 152. Example: Sandstone.

Field Name	Description and Action To Be Taken
Kind	Select secondary lithology code from Parent/Surficial Materials table on page 163.
Kind Modifier	Select modifier from the table on page 166 if kind needs to be further defined.
Weathering	Determine weathering state from the table on page 152. Example: PDS – Partially Decomposed.
Chemistry Modifier	Select appropriate term from the table on page 163. Example: AC – Acidic.
Size Class	Select appropriate term from the table on page 167. Example: 7 – Loamy.
Stratigraphy	Locally determined values for unit name and age. Example: Kbb – Blind Bull Formation.

Geologic Terms and Definitions

Bedrock Characteristics

Depth to Bedrock Class

Depth Class	Definition
DEEP	Deep – 10 to 20 feet deep
MOD	Moderate – 5 to 10 feet deep
SHAL	Shallow – < 5 feet deep
VDEP	Very deep – > 20 feet deep

Bedrock Weathering

Weathering Code	Meaning – Definition
MFS	Micro fresh state – absence of oxidation alteration under hand lens.
VFS	Visually fresh state – uniform color with unaided eye.
STS	Stained state – partial or complete discoloration of mineral.
PDS	Partially decomposed state – solid in place, disaggregate by hand.
CDS	Completely decomposed – disaggregated or remolded to soil.

Bedrock Lithologies

Primary Lithology	Secondary Code	Secondary Description
Igneous Extrusive	ANBA	Analcite Basalt
Igneous Extrusive	ANDE	Andesite
Igneous Extrusive	ANPO	Andesite Porphyry
Igneous Extrusive	BASA	Basalt
Igneous Extrusive	BAPO	Basalt Porphyry
Igneous Extrusive	BAAN	Basaltic Andesite
Igneous Extrusive	BASN	Basanite
Igneous Extrusive	DACI	Dacite
Igneous Extrusive	DAPO	Dacite Porphyry
Igneous Extrusive	FELS	Felsite
Igneous Extrusive	LATI	Latite
Igneous Extrusive	LAPO	Latite Porphyry
Igneous Extrusive	LEBA	Leucite Basanite
Igneous Extrusive	LEPH	Leucite Phonolite
Igneous Extrusive	LETE	Leucite Tephrite
Igneous Extrusive	LIMB	Limburgite
Igneous Extrusive	LIPO	Limburgite Porphyry

Primary Lithology	Secondary Code	Secondary Description
Igneous Extrusive	MELI	Melilitite
Igneous Extrusive	NELA	Nepheline Latite
Igneous Extrusive	NELAPO	Nepheline Latite Porphyry
Igneous Extrusive	NEPH	Nephelinite
Igneous Extrusive	OBSI	Obsidian
Igneous Extrusive	OCEA	Oceanite
Igneous Extrusive	OLBA	Olivine Basalt
Igneous Extrusive	OLNE	Olivine Nephelinite
Igneous Extrusive	PERL	Perlite
Igneous Extrusive	PHON	Phonolite
Igneous Extrusive	PHPO	Phonolite Porphyry
Igneous Extrusive	PITC	Pitchstone
Igneous Extrusive	PUMI	Pumice
Igneous Extrusive	QUBA	Quartz Basalt
Igneous Extrusive	QULA	Quartz Latite
Igneous Extrusive	QULAPO	Quartz Latite Porphyry
Igneous Extrusive	RHYO	Rhyolite
Igneous Extrusive	RHPO	Rhyolite Porphyry
Igneous Extrusive	SCOR	Scoria
Igneous Extrusive	TEPR	Tephrite
Igneous Extrusive	TEPO	Tephrite Porphyry
Igneous Extrusive	TING	Tinguaite
Igneous Extrusive	TRAC	Trachyte
Igneous Extrusive	TRPO	Trachyte Porphyry
Igneous Extrusive	TRAP	Trap
Igneous Extrusive	VITR	Vitrophyre
Igneous Extrusive	WYOM	Wyomingite
Igneous Intrusive	ALSK	Alaskite
Igneous Intrusive	ALGR	Alkali Granite
Igneous Intrusive	ALSY	Alkali Syenite
Igneous Intrusive	ANOR	Anorthosite
Igneous Intrusive	APLI	Aplite
Igneous Intrusive	CHAR	Charnockite
Igneous Intrusive	DIAB	Diabase
Igneous Intrusive	DIOR	Diorite
Igneous Intrusive	DIPO	Diorite Porphyry
Igneous Intrusive	DITR	Ditroite
Igneous Intrusive	DUNI	Dunite
Igneous Intrusive	FERG	Fergusite
Igneous Intrusive	FOYA	Foyaite
Igneous Intrusive	GABB	Gabbro

Primary Lithology	Secondary Code	Secondary Description
Igneous Intrusive	GAPO	Gabbro Porphyry
Igneous Intrusive	GADI	Gabbro/Diorite
Igneous Intrusive	GRAN	Granite
Igneous Intrusive	GRPO	Granite Porphyry
Igneous Intrusive	GRAO	Granodiorite
Igneous Intrusive	GDPO	Granodiorite Porphyry
Igneous Intrusive	GRGR	Graphic Granite
Igneous Intrusive	HARZ	Harzburgite
Igneous Intrusive	LAMP	Lamprophyre
Igneous Intrusive	LARV	Larvikite
Igneous Intrusive	LESY	Leucite Syenite
Igneous Intrusive	LUXU	Luxullianite
Igneous Intrusive	MALI	Malignite
Igneous Intrusive	MISS	Missourite
Igneous Intrusive	MONZ	Monzonite
Igneous Intrusive	MOPO	Monzonite Porphyry
Igneous Intrusive	NEMO	Nepheline Monzonite
Igneous Intrusive	NEMOPO	Nepheline Monzonite Porphyry
Igneous Intrusive	NESY	Nepheline Syenite
Igneous Intrusive	NESYPO	Nepheline Syenite Porphyry
Igneous Intrusive	NORD	Nordmarkite
Igneous Intrusive	NORI	Norite
Igneous Intrusive	OLGA	Olivine Gabbro
Igneous Intrusive	PEGM	Pegmattite
Igneous Intrusive	PERI	Peridotite
Igneous Intrusive	PICR	Picrite
Igneous Intrusive	PULA	Pulaskite
Igneous Intrusive	PYRO	Pyroxenite
Igneous Intrusive	QUDI	Quartz Diorite
Igneous Intrusive	QUDIPO	Quartz Diorite Porphyry
Igneous Intrusive	QUGA	Quartz Gabbro
Igneous Intrusive	QUMO	Quartz Monzonite
Igneous Intrusive	QUMOPO	Quartz Monzonite Porphyry
Igneous Intrusive	QUSY	Quartz Syenite
Igneous Intrusive	SHON	Shonikite
Igneous Intrusive	SOSY	Sodalite Syenite
Igneous Intrusive	SYEN	Syenite
Igneous Intrusive	SYPO	Syenite Porphyry
Igneous Intrusive	SYEO	Syenodiorite
Igneous Intrusive	THER	Theralite
Igneous Intrusive	THPO	Theralite Porphyry

Primary Lithology	Secondary Code	Secondary Description
Igneous Intrusive	TROC	Troctolite
Igneous Intrusive	UNCO	Uncompahgrite
Igneous Intrusive	UOLI	Uolite
Metamorphic	ACHO	Actinolite Hornfels
Metamorphic	ACMA	Actinolite Marble
Metamorphic	ACSC	Actinolite Schist
Metamorphic	ACEPMA	Actinolite-Epidote Marble

Bedrock Texture Modifiers

Code	Modifier	Definition
AMOR	Amorphous	Sediment or sed. rock composed of noncrystalline, authigenic material.
AMYG	Amygdaloidal	Igneous rock with vesicle fillings composed of secondary minerals.
APHA	Aphanitic	Igneous rock composed of grains not individually visible to unaided eye.

Code	Modifier	Definition
AUGE	Augen	Metamorph texture of larger eye-shaped mineral masses in finer grained matrix.
BIOC	Bioclastic	Composed of fragments of fossils.
BOUL	Bouldery	Sediment or sed. rock containing more than 15% particles with a diameter greater than 256 mm.
CATA	Cataclastic	Metamorph texture developed by severe mechanical crushing of the component grains.
CHEM	Chemical	Sediment or sed. rock rock composed primarily of material formed by precip. from soln or colloidal suspension.
CLAS	Clastic	Sediment or sed. rock composed of frags made of preexisting rocks or minerals transported from their origins.
COBB	Cobbly	Sediment or sed. rock with more than 15% rock fragments with a diameter between 64 mm and 256 mm.
CRYP	Cryptocrystalline	Rock composed of crystals or grains not visable with a microscope.
CRYS	Crystalline	Rock composed of interlocking mineral crystals or grains.
DETR	Detrital	Sediment or sed. rock rock composed mostly of particles eroded or weathered from preexisting rocks.
DIAB	Diabasic	Igneous rock composed of anhedral pyrox. between unoriented laths of plag.
EQUI	Equigranular	Igneous rock composed of grains of nearly uniform size.
FISS	Fissile	Sediment or sed. rock rock with very thin bedding planes easily split.
FLAS	Flaser	Metamorph rock with lenses of original minerals surrounded by highly sheared and crushed material.
FOLI	Foliation	Met. rock with planar structure that results from flattening the constituent grains.
GLAS	Glassy	Holohyaline igneous rock.
GNEI	Gneissose	Met. rock with foliation due to alteration of granulose and schistose bands.
GRAT	Granitic	Igneous rock composed of a mixture of anhedral and subhedral grains.
GRAN	Granular	Igneous rock composed of nearly equidimensional mineral xls.
GRAL	Granulose	Met. rock with granular texture with nondirectional structure.
GRAV	Gravelly	Sediment or sed. rock with at least 15% of particles between 2 mm and 10 mm in diameter.
HOLO	Holocrystalline	Igneous rock composed of essentially all crystalline grains.
HLHY	Holohyaline	Igneous rock that is essentially all glass.
HORN	Hornfelsic	Metamorph rock with nondirectional structure.

Code	Modifier	Definition
HYPH	Hypocrystalline	Igneous rock in part composed of glass.
LINE	Lineation	Met. rock with parallel directional structure of mineral grains.
MICR	Microcrystalline	Igneous rock composed of xls individually visible with a microscope.
MIGM	Migmatic	Metamorphic host rocks with granitic layers or lenses.
MYLO	Mylonitic	Met. rock with foliated, fine-grained cataclastic structure.
OOLI	Oolitic	Sediment or sed. rock composed of spheroids less than 2 mm in diameter.
OPHI	Ophitic	Igneous rock composed of plagioclase laths enclosed in plates of pyroxene.
PEBB	Pebbly	Sediment or sed. rock with more than 15% particles between 2 mm and 64 mm in diameter.
PEGM	Pegmatitic	Igneous rock composed of xls conspicuously larger than surrounding rock.
PHCG	Phan-coarse grained	Igneous rock composed of xls more than 5 mm in diameter.
PHFG	Phan-fine grained	Igneous rock composed of xls less than 1 mm in diameter.
PHMG	Phan-medium grained	Igneous rock composed of xls 1-5 mm in diameter.
PHAN	Phaneritic	Igneous rock composed of xls individually visible to the unaided eye. PHYL Phyllitic Met. rock with foliation intermediate between slaty and schistose.
PISO	Pisolitic	Sediment or sed. rock composed of spheroids greater than 2 mm in diameter.
PORP	Porphyritic	Igneous rock composed of larger xls in a fine-grained groundmass.
PUMI	Pumiceous	Igneous rock that is highly vesicular and finely cellular.
SAND	Sandy	Sediment or sed. rock with more than 15% grains between 1/16 mm and 2mm in diameter.
SCHI	Schistose	Met. rock with foliation due to parallel orientation of phan., flaky minerals.
SCOR	Scoriaceous	Igneous rock that is highly vesicular and coarsely cellular.
SILT	Silty	Sediment or sed. rock with more than 15% particles between 1/256 mm and 1/16 mm in diameter.
SLAT	Slaty	Met. rock with foliation in aphanitic metamorphic rocks.
SPHE	Spherulitic	Igneous rock with spherical bodies of xls.
VESI	Vesicular	Igneous rock with spherical, ovoid, or tubular openings (vesicles).

Bedrock and Surficial Materials Chemistry Modifiers

Code	Meaning	Definition
AC	Acidic	Igneous rocks or sediments that contain more than 65% SiO ₂ .
BA	Basic	Igneous rocks or sediments with a relatively low silica content: 44–53%.
CA	Calcareous	Rocks or sediments containing calcium carbonate up to 50%.
CB	Carbonaceous	Sediments that contain considerable original or introduced organic material.
IM	Intermediate	Igneous rocks or sediments transitional between basic and acidic, with silica content of 54–64%.
SI	Siliceous	Rocks or sediments containing abundant free silica (rather than silicate minerals).
UL	Ultrabasic	Igneous rocks or sediments with a silica content lower than 44%.

Bedrock Fracture Interval

Code	Meaning
1	< 10 cm between fractures.
2	10 cm to 45 cm between fractures.
3	45 cm to 1.0 m between fractures.
4	1.0 to 2.0 m between fractures.
5	> 2.0 m between fractures.

Geological Structure Type

Code	Meaning	Definition
BE	Bedding	Planar surfaces that visibly separate layers of stratified rock.
FA	Fold Axis	The line that, moved parallel to itself, generates the form of a fold.
FO	Foliation	Planar structure from flattening of the rock's constituent grains.
FT	Fault	Fracture or a zone of fractures along which displacement has occurred.
JO	Joint	Fracturing or parting in rock, without displacement.
LI	Lineation	Any linear structure in a rock; e.g., mineral streaking and stretching from compression.

Parent/Surficial Materials

Primary and Secondary Lithology

Primary Lithology	Secondary Code	Secondary Description	Definition
Unconsolidated	ALLU	Alluvium	Clastic material deposited by moving water.
Unconsolidated	ASLO	Ash/Loess Mixture	Mixed volcanic ash and wind-blown silt.

Primary Lithology	Secondary Code	Secondary Description	Definition
Unconsolidated	CIND	Cinders	Pyroclastic material > 2 mm in size.
Unconsolidated	COLL	Colluvium	Nonsorted materials deposited on or at the base of a slope through gravitational forces.
Unconsolidated	CRYO	Cryoturbate	Earth material moved or disturbed by frost action.
Unconsolidated	DIAM	Diamicton	Nonsorted or poorly sorted, noncalcareous, terrigenous sediment that contains a wide range of particle sizes.
Unconsolidated	DIEA	Diatomaceous Earth	Light-colored siliceous sediment, consisting chiefly of opaline frustules of the diatom.
Unconsolidated	EOLI	Eolian Deposit	Deposit of wind-blown sediment.
Unconsolidated	GLAC	Glacial Deposit	Material deposited by a glacier.
Unconsolidated	GLMO	Glacial Moraine Deposit	Distinct accumulation of unsorted, unstratified material deposited chiefly by direct action of glacial ice.
Unconsolidated	GLTI	Glacial Till Deposit	Unsorted and unstratified material deposited directly by and underneath a glacier without subsequent reworking by meltwater.
Unconsolidated	GLFL	Glaciofluvial Deposit	Material transported and deposited by running water emanating from a glacier.
Unconsolidated	GLLA	Glaciolacustrine Deposit	Deposit composed of suspended material brought by meltwater streams flowing into lakes bordering a glacier.
Unconsolidated	GLMA	Glaciomarine Deposit	Deposit composed of suspended material brought by meltwater streams flowing into seas bordering a glacier.
Unconsolidated	GRSA	Greensand	Marine sediment consisting largely of dark greenish grains of glauconite.
Unconsolidated	GYSA	Gypsum Sand	Sediment consisting primarily of gypsum particles > 0.05 mm.

Primary Lithology	Secondary Code	Secondary Description	Definition
Unconsolidated	HUCA	Human Caused/Constructed	Sediments deposited by direct human action.
Unconsolidated	LACU	Lacustrine Sediments	Deposit composed of suspended material brought by streams flowing into lakes.
Unconsolidated	LAHA	Lahar	Water-saturated volcanic materials that flowed down the volcano's slopes.
Unconsolidated	LADE	Landslide Deposit	Deposit of material resulting from the downslope transport, under gravitational influence, of soil and rock material en masse.
Unconsolidated	MARI	Marine Sediments	Deposit composed of suspended material brought by streams flowing into seas.
Unconsolidated	MARL	Marl	Deposits consisting chiefly of an intimate mixture of clay and calcium carbonate.
Unconsolidated	MIXE	Mixed	Deposits of undifferentiated materials.
Unconsolidated	MUCK	Muck	Dark, finely divided, well-decomposed organic material, intermixed with a high percentage of mineral matter, usually silt.
Unconsolidated	ORGA	Organic Deposits	Deposit in which carbon is an essential, substantial component.
Unconsolidated	PEAT	Peat	Deposit of semicarbonized plant remains in a water-saturated environment.
Unconsolidated	RESI	Residium	Deposit of rock debris formed by weathering, remaining essentially in place after all but the least soluble constituents have been removed.
Unconsolidated	TALU	Talus Deposit	Rock fragments of any size or shape (usually coarse and angular) derived from and lying at the base of a cliff or very steep, rocky slope.

Primary Lithology	Secondary Code	Secondary Description	Definition
Unconsolidated	TEPH	Tephra (Undifferentiated)	Deposit of particles ejected during a volcanic eruption.
Unconsolidated	TRAN	Transitional Marine/Continental Deposits	Undifferentiated materials deposited at or near the land/sea interface.
Unconsolidated	VOAS	Volcanic Ash	Pyroclastic material under 2 mm diameter.

Parent/Surficial Materials Modifiers

Modifier	Modifies	Modifier Definition
Creep	Colluvium	Deposit of earthy materials accumulating at or near a slope base through slow gravitational movement.
Scree	Colluvium	Deposit of coarse, rock debris mantling a slope with no rock overhang or cliff.
Dune Sand	Eolian Deposit	Wind-blown deposit composed of material > 0.05 mm in diameter.
Loess	Eolian Deposit	Wind-blown deposit composed of material < 0.05 mm in diameter.
Ablation	Glacial Till Deposit	Till deposited through down-wasting of a glacier (also called supraglacial).
Basal	Glacial Till Deposit	Till deposited at the base of a moving glacier (also called subglacial, lodgement, melt-out, flow).
Block Glide	Landslide Deposit	Deposit of largely intact rock/earth units that slid downslope along a planar surface.
Debris Avalanche	Landslide Deposit	Deposit of mixed rock and earth that moved rapidly-downslope as a dry, incoherent mass.
Debris Flow	Landslide Deposit	Deposit of mixed rock, earth, and mud (> 50% > 2 mm in size) that moved rapidly downslope as a wet to saturated, incoherent mass.
Debris Slide	Landslide Deposit	Hummocky deposit of mixed rock and earth that slid or rolled downslope as a relatively dry mass.
Earth Flow	Landslide Deposit	Deposit of mixed earth, mud, and rock (> 50% < 2 mm in size) that moved rapidly downslope as a wet to saturated, incoherent mass (also called mudflow).
Rockfall	Landslide Deposit	Deposit that accumulates at the base of a cliff from detached bodies of rock free-falling from above.
Rockfall Avalanche	Landslide Deposit	Deposit resulting from a massive rockfall that triggers an avalanche as it continues to the base of a slope and beyond.
Solifluction	Landslide Deposit	Deposit of water-saturated regolith that flowed slowly downslope; commonly occurring in frozen or permafrost terrain.
Topple	Landslide Deposit	Deposit created when a large block of rock falls over, rotating away from a low pivot point, and breaks apart.

Modifier	Modifies	Modifier Definition
Coprogenic	Organic Deposit	Deposit composed primarily of fecal material derived from aquatic animals.
Grassy	Organic Deposit	Deposit composed mostly of grassy materials.
Herbaceous	Organic Deposit	Deposit composed mostly of sedges, reeds, cattails, etc.
Mossy	Organic Deposit	Deposit composed mostly of mossy (e.g., sphagnum) materials.
Woody	Organic Deposit	Deposit composed mostly of woody debris.

Parent/Surficial Material Size Classes

Code	Meaning	Definition
1	Clayey	> 40% of material is clay (< .002 mm in diameter).
2	Coarse-loamy	> 15% of particles are 0.1 to 76 mm and < 18% of material is clay.
3	Coarse-silty	Material is < 18% clay, and < 15% of particles are 0.1 to 76 mm in size.
4	Fine-loamy	Material is 18 to 35% clay and > 15% of particles are 0.1 to 76 mm in diameter.
5	Fine-silty	Material is 18 to 35% clay and < 15% particles are .1 to 76 mm in size.
6	Gravelly	Material contains 15% or more rock fragments (particles between 2 and 76 mm in diameter).
7	Loamy	Material is 7 to 27% clay, 28 to 50% silt, and < 52% sand.
8	Sandy	At least 70% sand (between 0.05 and 2 mm in diameter).
9	Sandy and gravelly	At least 70% sand and 15% gravel.
10	Sandy and silty	At least 15% of grains between .05 and 2 mm in diameter, and 15% of grains between .002 mm and .05 (sand or loamy sand and silt or silt loam).
11	Silty	> 50% of particles between 0.02 and 0.5 mm in diameter.
12	Silty and clayey	> 40% of material is clay and > 40% is silt.
13	Stony	> 50% of particles between 250 and 600 mm in diameter.
14	Bouldery	> 50% of particles larger than 600 mm in diameter.
15	Cobbly	> 50% of particles between 76 and 250 mm in diameter.

Soil Pedon Description Form Instructions

Soil Pedon Description Form

Field Name	Description and Action To Be Taken
Site ID	Record the identifier that is unique within a specific project or inventory area.
Map Unit Symbol	Enter the map unit symbol (if known), typically a two- or three-digit number, in which the site occurs.
Date	Enter the date the profile was described in MMDDYYYY. Example: 07081997.
Examiner	Enter the name of the person(s) describing the site.
Soil Classification	Use the most recent edition of <i>Keys to Soil Taxonomy</i> (USDA NRCS 2003a) and enter the soil classification. Example: loamy-skeletal, mixed Typic Cryalfs.
Family or Series	Enter the family name or series name. Indicate the latter by drawing a circle around the word(s) "Family" or "Series," respectively.
Taxonomic Modal	Enter Yes or No if this is the modal pedon description for the taxonomic unit (ecological type).
Erosion	A. Kind: Wind – Deflation by wind. Water: S – sheet. Even soil loss, no channels. R – rill. Small channels. G – gully. Big channels. T – tunnel. Subsurface voids within soil that enlarge by running water (i.e., piping). B. Degree class. Estimated % loss of the original A & E horizons or the estimated loss of the upper 20 cm (if original, combined A & E horizons were < 20 cm thick). Class 0: 0% Class 1: > 0 up to 25% Class 2: 25 up to 75% Class 3: 75 up to 100% Class 4: > 75% and total removal of A (Schoeneberger et al. 2002, 1–23)
Water Table	Measure or estimate the depth from the ground surface to the stabilized contact with free-standing water in an open bore hole or well. a. Kind: AP – apparent. Level of stabilized water in a fresh, unlined borehole. PE – perched. A water table that lies above an unsaturated zone. The water table will fall if the borehole is extended.

Field Name	Description and Action To Be Taken																																	
Depth to Lithic or Paralithic Contact	b. Depth: Measurement in cm of the depth to water table. (Schoeneberger et al. 2002, 1-14)																																	
	Lithic Contact. The boundary between soil and a coherent underlying material. Except in Ruptic-Lithic subgroups, the underlying material must be virtually continuous within the limits of the pedon. Cracks that can be penetrated by roots are few, and their horizontal spacing is 10 cm or more. The underlying material must be sufficiently coherent when moist to make hand digging with a spade impractical, although the material may be chipped or scraped with a spade (USDA NRCS 2003a).																																	
	Paralithic Contact. A paralithic contact is a contact between soil and paralithic materials in which the paralithic materials have no cracks or the spacing of the cracks that roots can enter is 10 cm or more. Paralithic materials are relatively unaltered materials that have an extremely weakly cemented to moderately cemented rupture-resistance (USDA NRCS 2003a). Root Restricting Depth. The root restricting depth is where root penetration would be strongly inhibited because of physical and/or chemical characteristics. (Soil Survey Division Staff 1993). Restriction kinds include: <table> <tr><td>ABR</td><td>Abrupt textural change</td></tr> <tr><td>CALC</td><td>Petrocalcic</td></tr> <tr><td>CTEX</td><td>Strongly contrasting textural stratification</td></tr> <tr><td>DENS</td><td>Dense material</td></tr> <tr><td>DUR</td><td>Duripan</td></tr> <tr><td>FE</td><td>Petroferric</td></tr> <tr><td>FPAN</td><td>Fragipan</td></tr> <tr><td>IRON</td><td>Plinthite</td></tr> <tr><td>LITH</td><td>Bedrock (lithic)</td></tr> <tr><td>NATR</td><td>Natric</td></tr> <tr><td>ORST</td><td>Ortstein</td></tr> <tr><td>PARA</td><td>Bedrock (paralithic)</td></tr> <tr><td>PERM</td><td>Permafrost</td></tr> <tr><td>PGYP</td><td>Petrogypsic</td></tr> <tr><td>PLAC</td><td>Placic</td></tr> <tr><td>SAL</td><td>Salic</td></tr> <tr><td>SULF</td><td>Sulfuric</td></tr> </table>	ABR	Abrupt textural change	CALC	Petrocalcic	CTEX	Strongly contrasting textural stratification	DENS	Dense material	DUR	Duripan	FE	Petroferric	FPAN	Fragipan	IRON	Plinthite	LITH	Bedrock (lithic)	NATR	Natric	ORST	Ortstein	PARA	Bedrock (paralithic)	PERM	Permafrost	PGYP	Petrogypsic	PLAC	Placic	SAL	Salic	SULF

SULF	Sulfuric																																	
Surface Runoff Class	Surface Runoff. The flow of water from an area that occurs over the surface to the soil. Surface runoff differs from internal flow or throughflow that results when infiltrated water moves laterally or vertically																																	

Field Name	Description and Action To Be Taken
	within a soil, above the water table. The Index Surface Runoff Classes are relative estimates of surface runoff based on slope gradient and saturated hydraulic conductivity. This index is specific to the following conditions: • The soil surface is assumed to be bare. • The soil is free of ice. • Retention of water by ground surface irregularities is negligible or low. • Infiltration is assumed to be at the steady ponded infiltration stage. • Water is added to the soil by precipitation or snowmelt that yields 50 mm in 24 hours with no more than 25 mm in any 1-hour period. • Antecedent soil water state is assumed to be very moist or wet to: (a) the base of the solum, (b) a depth of 1 m, or (c) through the horizon that has the minimum Ksat within the top 1 meter; whichever is the least depth. Use table E.1 and the above conditions to estimate the Index Surface Runoff Class for the site. If seasonal or permanent, internal free water occurs at a depth of ≤ 50 cm (very shallow and shallow internal free water classes), use a Ksat of Very Low. If seasonal or permanent, internal free water is deeper than 50 cm, use the appropriate Ksat from the table (Schoeneberger et al. 2002, 1-24).

Index of Surface Runoff Classes						
Saturated Hydraulic Conductivity (Ksat) Class						
Slope Gradient Percent	Very High	High	Mod. High	Mod. Low	Low	Very Low
cm/hour	> 36	3.6 – < 36	0.36 – < 3.6	0.036 – < 0.36	0.0036 – < 0.036	< 0.0036
Concave ^a	N	N	N	N	N	N
< 1	N	N	N	L	M	H
1–5	N	LV	L	M	H	HV
5–10	LV	L	M	H	HV	HV
10–20	LV	L	M	H	HV	HV
> 20	LV	L	M	H	HV	HV

Table E.1. *Index Surface Runoff Classes based on slope gradient and saturated hydraulic conductivity (adapted from Schoeneberger et al. 2002, 1–24).*

Negligible – N; Very Low – LV; Low – L; Medium – M; High – H; Very High – HV

^a Areas from which little or no water escapes by flow over the ground surface.

Field Name	Description and Action To Be Taken
Soil Temperature	Measure the soil temperature at 50 cm and enter the degrees F. If a restrictive layer is encountered above 50 cm, record the depth and temperature at the maximum depth possible. Soil temperature should be read as soon as the soil pit is excavated.
Diagnostic Horizons	a. Surface. Use the current edition of <i>Keys to Soil Taxonomy</i> (USDA NRCS 2003a) to determine the surface diagnostic horizon. b. Subsurface. Use the current edition of <i>Keys to Soil Taxonomy</i> (USDA NRCS 2003a) to determine the subsurface diagnostic horizons.
Box Sampled	Enter Yes or No if a box sample of the pedon was collected.
Lab Sampled	Enter Yes or No if a lab sample was collected.
Particle Size Control Section	a. Depth. Enter the depth range for the particle size control section. Example: 20–40 inches. b. Avg. Clay and Avg. RF Content. Enter the weighted average rock fragments by volume and the weighted average clay by weight. The weighted average is calculated by multiplying the percentage of rock fragments or clay in each horizon by the thickness of the horizon, then adding the total percentage and dividing by the total thickness of the control section.
Drainage Class	Use the following definitions (USDA NRCS 1993, 98-99) to determine the drainage class: ED—Excessively Drained. Water is removed very rapidly. The occurrence of internal free water commonly is very rare or very deep. The soils are commonly coarse-textured and have very high-saturated hydraulic conductivity or are very shallow. SE—Somewhat Excessively Drained. Water is removed from the soil rapidly. Internal free water occurrence commonly is very rare or very deep. The soils are commonly coarse-textured and have high-saturated hydraulic conductivity or are very shallow. WD—Well Drained. Water is removed from the soil readily but not rapidly. Internal free water occurrence commonly is deep or very deep; annual duration is not specified. Water is available to plants throughout most of the growing season in humid regions. Wetness does not inhibit growth of roots for significant periods during most growing seasons. The soils are mainly free of the deep to redoximorphic features that are related to wetness. MW—Moderately Well Drained. Water is removed from the soil somewhat slowly during some periods of the year. Internal free occurrence commonly is moderately deep and transitory through permanent. The soils are wet for only a short time within the rooting depth during the growing season, but long enough that most mesophytic crops are affected. They commonly have a moderately low or lower saturated hydraulic conductivity in a layer within the upper 1 m, periodically receive high rainfall, or both.

Field Name	Description and Action To Be Taken
	SP—<i>Somewhat Poorly Drained</i>. Water is removed slowly so that the soil is wet at a shallow depth for significant periods during the growing season. The occurrence of internal free water commonly is shallow to moderately deep and transitory to permanent. Wetness markedly restricts the growth of mesophytic crops, unless artificial drainage is provided. The soils commonly have one or more of the following characteristics: low or very low saturated hydraulic conductivity, a high water table, additional water from seepage, or nearly continuous rainfall. PD—<i>Poorly Drained</i>. Water is removed so slowly that the soil is wet at shallow depths periodically during the growing seasons or remains wet for long periods. The occurrence of internal free water is shallow or very shallow and common or persistent. Free water is commonly at or near the surface long enough during the growing season so that most mesophytic crops cannot be grown, unless the soil is artificially drained. The soil, however, is not continuously wet directly below plow-depth. Free water at shallow depth is usually present. This water table is commonly the result of low or very low saturated hydraulic conductivity or nearly continuous rainfall, or of a combination of these. VP—<i>Very Poorly Drained</i>. Water is removed from the soil so slowly that free water remains at or very near the ground surface during much of the growing season. The occurrence of internal free water is very shallow and persistent or permanent. Unless the soil is artificially drained, most mesophytic crops cannot be grown. The soils are commonly level or depressed and frequently ponded. If rainfall is high or nearly continuous, slope gradients may be greater.

Horizon

Field Name	Description and Action To Be Taken
Hor. Seq. #	The horizon sequence number used when entering the data in a database. The number 1 implies the 1st horizon.
Horizon Designation	Using the current edition of <i>Keys to Soil Taxonomy</i> (USDA NRCS 2003a), enter the appropriate symbol and suffix(es) for each horizon.
Depth	Enter the thickness of each layer in cm, using the surface of the mineral soil as the base from which to measure. Example: 0–8 cm; 8–18 cm; 18–40 cm; 40–60 cm. Duff layers recorded in reverse depths. Example: 2–0.
Boundary	A surface or transitional layer between two adjoining horizons or layers. Most boundaries are zones of transition rather than sharp lines of division. Boundaries vary in distinctness and in topography.

Distinctness

Code	Meaning	Description
V	Very abrupt	< 0.5 cm
A	Abrupt	0.5 to 2 cm thick
C	Clear	2 to 5 cm thick
G	Gradual	5 to 15 cm thick
D	Diffuse	More than 15 cm thick

Table E.2. *Boundary distinctness codes.*

Topography

Code	Meaning	Description
S	Smooth	The boundary is a plane with few or no irregularities.
W	Wavy	The boundary has undulations in which the depressions are wider than they are deep.
I	Irregular	The boundary has pockets that are deeper than they are wide.
B	Broken	One or both of the horizons or layers separated by the boundary are discontinuous and the boundary is interrupted.

Table E.3. *Boundary topography codes.*

Soil Color

Field Name	Description and Action To Be Taken
Soil Color and Mottles	The <i>Soil Survey Manual</i> (USDA NRCS 1993) states that the elements of soil descriptions are “the color name, the Munsell notation, the water state, and the physical state: brown (10YR 5/3), dry, crushed and smoothed.” Physical state is recorded as broken, rubbed, crushed, or crushed and smoothed. The term “crushed” usually applies to dry samples and “rubbed” to moist samples. If unspecified, the surface is broken. The color of the soil is recorded for a surface broken through a ped if a ped can be broken as a unit. The color value of most soil material becomes lower after moistening. Consequently, the water state of a sample is always given. The water state is either moist or dry. The dry state for color determinations is air-dry and should be made at the site where the color does not change with additional drying. Color in the moist state is determined on moderately moist or very moist soil material and should be made at the point where the soil color does not change with additional moistening.

Field Name	Description and Action To Be Taken
	Mottling refers to repetitive color changes that cannot be associated with compositional properties of the soil. Redoximorphic features are a type of mottling that is associated with wetness. A color pattern that can be related to proximity to a ped surface or other organizational or compositional feature is not mottling. Mottling description follows the dominant color. Mottles are described by quantity, size, contrast, color, and other attributes, in that order.

Redoximorphic Features

Type of feature	Code	Meaning
Redox features	CLD	Clay depletions
Redox features	F2M	Masses of reduced iron (Fe+2) accumulation
Redox features	F3M	Masses of oxidized iron (Fe+3) accumulation
Redox features	FED	Iron depletions
Redox features	FEF	Ferriargillan coats (Fe+3 stained clay films)
Redox features	FMC	Iron-manganese concretions
Redox features	FMM	Masses of iron-manganese accumulation
Redox features	FMN	Iron-manganese nodules
Redox features	FSN	Ironstone nodules
Redox features	MNF	Manganese surface coats/films or hypocoats
Redox features	MNM	Masses of manganese accumulation
Redox features	PLN	Plinthite nodules
Redox features	RC	Redoximorphic concentrations (undifferentiated)
Redox features	RD	Redoximorphic depletions (undifferentiated)
Redox features	RMX	Reduced matrix

Quantity and Size Classes

Code	Meaning	Description
F	Few	Less than 2 percent
C	Common	2 to 20 percent
M	Many	More than 20 percent

Table E.5. *Quantity classes.*

Code	Meaning	Description
F	Fine	Smaller than 5 mm
M	Medium	5 to 15 mm
C	Coarse	Larger than 15 mm

Table E.6. *Size classes.*

Contrast

Contrast refers to the degree of visual distinction evident between associated colors.

Code	Meaning	Description
F	Faint	Evident only on close examination. Faint mottles commonly have the same hue as the color to which they are compared, and differ by no more than 1 unit of chroma or 2 units of value. Some faint mottles of similar but low chroma and value differ by 2.5 units (1 card) of hue.
D	Distinct	Readily seen, but contrast only moderately with the color to which they are compared. Distinct mottles commonly have the same hue as the color to which they are compared, but differ by 2 to 4 units of chroma or 3 to 4 units of value; or differ from the color to which they are compared by 2.5 units (1 card) of hue, but by no more than 1 unit of chroma or 2 units of value.
P	Prominent	Contrast strongly with the color to which they are compared. Prominent mottles are commonly the most obvious color feature of the section described. Prominent mottles that have medium chroma and value commonly differ from the color to which they are compared by at least 5 units (2 pages) of hue if chroma and value are the same; at least 4 units of value or chroma if the hue is the same; or at least 1 unit of chroma or 2 units of value if hue differs by 2.5 units (1 card).

Table E.7. *Contrast codes.*

Location of Redoximorphic and Mottles.

Code	Meaning	Description
Redox features	CRK	Cracks
Redox features	BRF	On bottom of rock fragments
Redox features	BPF	Between peds
Redox features	MPO	Infused into the matrix adjacent to pores (hypocoating)
Redox features	MAT	Matrix adjacent to pores
Redox features	MAC	Matrix surrounding redox concentrations
Redox features	MAD	Matrix surrounding redox depletions
Redox features	MPF	Matrix
Redox features	APF	Ped faces
Redox features	HPF	Ped horizontal faces
Redox features	VPF	Ped vertical faces
Redox features	LPO	Pore lining
Redox features	ARF	Around rock fragments

>600 mm long	Boulders	Bouldery	BY

Table E.10. *Rock fragment terms.*

Texture Modifier Classes

- *Less than 15 percent.* No terms are used for contrast with soils having less than 15 percent pebbles, cobbles, or flagstones. The adjective “slightly” may be used, however, to recognize those soils used for special purposes.
- *15 to < 35 percent.* The adjectival term of the dominant kind of rock fragment is used as a modifier of the textural term: “gravelly loam (GRL),” “channery loam (CNL),” “cobbly loam (CBL).”
- *35 to < 60 percent.* The adjectival term of the dominant kind of rock fragment is used with the word “very (V)” as a modifier of the textural term: “very gravelly loam (GRVL),” “very flaggy loam (FLV).”
- *60 to < 90 percent.* If enough fine earth is present to determine the textural class (approximately 10 percent or more by volume) the adjectival term of the dominant kind of rock fragment is used with the word “extremely (X)” as a modifier of the textural term: “extremely gravelly loam (GRXL),” “extremely bouldery loam (BYXL).” If there is too little fine earth to determine the textural class (less than 10 percent by volume), the term “gravel,” “cobbles,” “stones,” or “boulders” is used as appropriate.

Code	Meaning	Code	Meaning
BY	Bouldery	PBY	Parabouldery
BYV	Very Bouldery	PBYV	Very parabouldery

Table E.12. *Compositional texture modifiers.*

Terms Used in Lieu of Texture

Terms used in lieu of texture are substitute terms applied to materials that do not fit into a texture class because of organic matter content, size, rupture resistance, solubility, or another reason. Examples include muck, duripan, gravel, and bedrock.

Code	Meaning	Code	Meaning
BR	Bedrock	PC	Petrocalcic
BY	Boulders	PCB	Paracobbles
CB	Cobbles	PCN	Parachanners
CN	Channers	PEAT	Peat
DUR	Duripan	PF	Petroferric
FL	Flagstones	PFL	Paraflagstones
GR	Gravel	PG	Paragravel
HPM	Highly decomposed plant material	PGP	Petrogypsic
MAT	Material	PL	Placic
MPM	Moderately decomposed plant material	PST	Parastones
MPT	Mucky peat	SPM	Slightly decomposed
MUCK	Muck	ST	Stones
OR	Ortstein	W	Water
PBY	Paraboulders plant material		

Table E.13. *Terms used in lieu of texture.*

Structure

Field Name	Description and Action To Be Taken
Structure (Shape, size, and grade)	Soil structure refers to units composed of primary particles. The cohesion within these units is greater than the adhesion among units. As a consequence, under stress, the soil mass tends to rupture along predetermined planes or zones. Some soils lack structure and are referred to as structureless. In structureless layers or horizons, no units are observable in place or after the soil has been gently disturbed, such as by tapping a spade containing a slice of soil against a hard surface or dropping a large fragment on the ground. (USDA NRCS 1993, 157-163). In soils that have structure, the shape, size, and grade (distinctness) of the units are described. Field terminology for soil structure consists of separate sets of terms designating each of the three properties, which by combination form the names for structure.

Field Name	Description and Action To Be Taken
	Shape. Several basic shapes of structural units are recognized in soils. Supplemental statements about the variations in shape of individual peds are needed in detailed descriptions of some soils. The following terms describe the basic shapes and related arrangements: Platy. The units are flat and platelike. They are generally oriented horizontally. A special form, lenticular platy structure, is recognized for plates that are thickest in the middle and thin toward the edges. Prismatic. The individual units are bounded by flat to rounded vertical faces. Units are distinctly longer vertically, and the faces are typically casts or molds of adjoining units. Vertices are angular or subrounded; the tops of the prisms are somewhat indistinct and normally flat. Columnar. The units are similar to prisms and are bounded by flat or slightly rounded vertical faces. The tops of the columns, in contrast to those of prisms, are very distinct and normally rounded. Blocky. The units are blocklike or polyhedral. They are bounded by flat or slightly rounded surfaces that are casts of the faces of surrounding peds. Typically, blocky structural units are nearly equidimensional but grade to prisms and to plates. The structure is described as angular blocky if the faces intersect at relatively sharp angles; it is described as subangular blocky if the faces are a mixture of rounded and plane faces and the corners are mostly rounded.

Code	Description	Code	Description
ABK	Angular blocky	PL	Platy
CDY	Cloddy	PR	Prismatic
COL	Columnar	SGR	Single grain
GR	Granular	SBK	Subangular blocky
LP	Lenticular platy	WEG	Wedged shaped aggregates
MA	Massive		

Table E.14. *Structure shape codes.*

Size. Five classes are employed: very fine, fine, medium, coarse, and very coarse. The size limits of the classes differ according to the shape of the units. The size limits refer to the smallest dimension of the plates, prisms, and columns. If the units are more than twice the minimum size of “very coarse,” the actual size is given: “prisms 30 to 40 cm across.” In describing plates, “thin” is used instead of “fine” and “thick” instead of “coarse.”

Size Classes	Platy	Prismatic and Columnar	Blocky	Granular
Very fine	< 1 mm	< 10 mm	< 5 mm	< 1 mm
Fine	1–2 mm	10–20 mm	5–10 mm	1–2 mm
Medium	2–5 mm	20–50 mm	10–20 mm	2–5 mm
Coarse	5–10 mm	50–100 mm	20–50 mm	5–10 mm
Very coarse	> 10 mm	> 100 mm	> 50 mm	> 10 mm

Table E.15. *Structural size classes.*

Code	Description	Code	Description	Code	Description
VN	Very thin	F	Fine	VC	Very coarse
TN	Thin	M	Medium	VF	Very fine
TK	Thick	C	Coarse	EC	Extremely coarse
VK	Very thick				

Table E.16. *Size codes.*

Grade. Grade describes the distinctness of the units. Criteria are the ease of separation into discrete units and the proportion of the units that hold together when the soil is handled. Three classes are used:

1. **Weak.** The units are barely observable in place. When gently disturbed, the soil material parts into a mixture of whole and broken units and much material that exhibits no planes of weakness. Faces that indicate persistence through wet-dry cycles are evident if the soil is handled carefully. Distinguishing structurelessness from weak structure is sometimes difficult. Weakly expressed structural units in virtually all soil materials have surfaces that differ in some way from the interiors.
2. **Moderate.** The units are well formed and evident in undisturbed soil. When disturbed, the soil material parts into a mixture of mostly whole units, some broken units, and material that is not in units. Peds part from adjoining peds to reveal nearly entire faces that have properties distinct from those of fractured surfaces.
3. **Strong.** The units are distinct in undisturbed soil. They separate cleanly when the soil is disturbed. When removed, the soil material separates mainly into whole units. Peds have distinctive surface properties.

Code	Description
1	Weak
2	Moderate
3	Strong
0	Structureless

Table E.17. *Grade codes.*

Compound structure occurs when smaller units may be held together to form larger units. Grade, size, and shape are given for both and the relationship of one set to the other is indicated: “strong medium blocks within moderate coarse prisms,” or “moderate coarse prismatic structure parting to strong medium blocky.”

Consistence

Field Name	Description and Action To Be Taken
Consistence	Soil consistence (USDA NRCS 1993, 172-183) refers to “attributes of soil material as expressed in degree of cohesion and adhesion or in resistance to deformation on rupture.” As employed here, consistence includes: (1) resistance of soil material to rupture, (2) resistance to penetration, (3) plasticity, toughness and stickiness of puddled soil material, and (4) the manner in which the soil material behaves when subject to compression. Consistency is highly dependent on the soil-water state and the description has little meaning unless the water state class is specified or is implied by the test. Previously class sets were given for “dry” and “moist” consistence of the soil material as observed in the field. “Wet” consistence was evaluated for puddled soil material. Here the terms used for “moist” consistence previously are applied to the wet state as well. Stickiness, plasticity, and toughness of the puddled soil material are independent tests.

Classes			Test Description
Moderately dry and very dry	Slightly dry and wetter	Air dried, submerged	Operation.
Loose	Loose	Not applicable	Specimen not obtainable.
Soft	Very friable	Noncemented	Fails under very slight force applied slowly between thumb and forefinger.
Slightly hard	Friable	Extremely weakly Cemented	Fails under slight force applied slowly between thumb and forefinger.
Moderately hard	Firm	Very weakly cemented	Fails under moderate force applied slowly between thumb and forefinger.
Hard	Very firm	Weakly cemented	Fails under strong force applied slowly between thumb and forefinger.
Very hard	Extremely firm	Moderately cemented	Cannot be failed between thumb and forefinger but can be between both hands or by placing on a nonresilient surface and applying gentle force underfoot.

Classes			Test Description
Extremely hard	Slightly rigid	Strongly cemented	Cannot be failed in hands but can be underfoot by full body weight applied slowly.
Rigid	Rigid	Very strongly cemented	Cannot be failed underfoot by full body weight but can be by < 3 Joules blow.*
Very rigid	Very rigid	Indurated	Cannot be failed by a blow > 3 Joules.

Table E.18. *Rupture resistance for blocklike specimens.*

*One joule is the energy delivered by dropping a 1 kg weight 10 cm.

Code	Description	Code	Description	Code	Description
EH	Extremely hard	MH	Moderately hard	S	Soft
HA	Hard	R	Rigid	VH	Very hard
L	Loose	SH	Slightly hard	VR	Very rigid

Table E.19. *Moderately dry and very dry blocklike specimens.*

FR	Friable	SR	Slightly rigid	VR	Very rigid

Table E.20. *Slightly dry and wetter blocklike specimens.*

Code	Description	Code	Description
EW	Extremely weakly cemented	S	Strongly cemented
I	Indurated	VS	Very strongly cemented
M	Moderately cemented	VW	Very weakly cemented
NA	Nonapplicable	W	Weakly cemented
N	Noncemented		

Table E.21. *Air dried, submerged blocklike specimens.*

Stickiness

Stickiness refers to the capacity of a soil to adhere to other objects. The determination is made on puddled < 2 mm soil material at the water content at which the material is most sticky. The sample is crushed in the hand; water is applied while manipulation is contained between thumb and forefinger until maximum stickiness is reached. The classes in the table below are used to describe stickiness.

Code	Classes	Test Description
SO	Nonsticky	After release of pressure, practically no soil material adheres to thumb or forefinger.
SS	Slightly sticky	After release of pressure, soil material adheres perceptibly to both digits. As the digits are separated, the material tends to come off one or the other rather cleanly. The material does not stretch appreciably on separation of the digits.
MS	Moderately sticky	After release of pressure, soil material adheres to both digits and tends to stretch slightly rather than pull completely free from either digit.
VS	Very sticky	After release of pressure, soil material adheres so strongly to both digits that it stretches decidedly when the digits are separated. Soil material remains on both digits.

Table E.22. *Stickiness codes.*

Plasticity

Plasticity is the degree to which a puddled soil material is permanently deformed without rupturing by force applied continuously in any direction. Plasticity is determined on material smaller than 2 mm.

The determination is made on thoroughly puddled soil material at a water content where maximum plasticity is expressed. This water content is above the plastic limit, but it is less than the water content at which maximum stickiness is expressed. The water content is adjusted by adding water or removing it during manipulation. The closely related plastic limit, used in engineering classifications, is the water content for < 0.4 mm material at which a roll of 3 mm in diameter which had been formed at a higher water content breaks apart.

Code	Classes	Test Description
PO	Nonplastic	A roll 4 cm long and 6 mm thick that supports its own weight held on end cannot be formed.
SP	Slightly plastic	A roll 4 cm long and 6 mm thick can be formed and, if held on end, will support its own weight. A roll 4 mm thick will not support its own weight.
MP	Moderately	A roll 4 cm long and 4 mm thick can be formed and will support plastic its own weight, but a roll 2 mm thick will not support its own weight.
VP	Very plastic	A roll 4 cm long and 2 mm thick can be formed and will support its own weight.

Table E.23. *Plasticity codes.*

Code	Classes	Test Description
Brittleness		Press a 3 cm block between thumb and forefinger).
B	Brittle	Ruptures abruptly (“pops” or shatters).
SD	Semi-deformable	Rupture occurs after compression to > or = to ? original thickness.
D	Deformable	Rupture occurs after compression to > or = to ? original thickness.
Fluidity		Squeeze a palmful of soil in hand.
NF	Nonfluid	No soil flows through fingers with full compression.
SF	Slightly fluid	Some soil flows through fingers, most remains in the palm, after full pressure.
MF	Moderately fluid	Most soil flows through fingers, some remains in palm, after full pressure.
VF	Very fluid	Most soil flows through fingers, very little remains in palm, after gentle pressure.
Smeariness ¹		Press a 3 cm block between thumb and forefinger.
NS	Nonsmeary	At failure, the sample does not change abruptly to fluid, fingers do not skid, no smearing occurs.
WS	Weakly smeary	At failure, the sample changes abruptly to fluid, fingers skid, soil smears, little or no water remains on fingers.
MS	Moderately smeary	At failure, the sample changes abruptly to fluid, fingers skid, soil smears, some water remains on fingers.
SS	Strongly smeary	At failure, the sample changes abruptly to fluid, fingers skid, soil smears and is slippery, water easily seen on fingers.

¹ Smeary failure classes are used dominantly with Andic materials, but may also be used with some spodic materials.

Special Features

Field Name	Description and Action To Be Taken
Special Features	Films. The kinds of special surface features are clay films (or clay skins), clay bridges, sand or silt coats, other coats, stress surfaces (pressure faces), and slickensides. The various surface features may be on some or all structural units, channels, pores, primary particles or grains, soil fragments, rock fragments, nodules, or concretions. The kind and orientation of surface on which features are observed is always given. For example, if clay films are on vertical but not horizontal faces of peds, this fact should be recorded.

Feature	Code	Description
Surface features	BRF	Clay bridging
Surface features	CAF	Carbonate coats
Surface features	CLF	Clay films
Surface features	CT	Coats (undifferentiated)
Surface features	CTOX	Oxide coats
Surface features	FEF	Iron stains
Surface features	GBF	Gibbsite coats
Surface features	MNF	Manganese stains
Surface features	NNS	Nonintersecting slickensides
Surface features	OAF	Organoargillans
Surface features	OSF	Organic stains
Surface features	PRF	Pressure faces
Surface features	SAF	Skeletans on argillans
Surface features	SIF	Silica (silans, opal)
Surface features	SKF	Skeletans (sand or silt)
Surface features	SLF	Silt coats
Surface features	SNF	Sand coats
Surface features	SS	Slickensides (pedogenic)
Surface features	SSG	Slickensides (geogenic)
Surface features	STIR	Iron-manganese stains
Surface features	STSB	Black stains

Table E.24. *Ped surface feature kinds.*

Amount

The amount, or percentage, of the total surface area of the kind of surface considered occupied by a particular surface feature over the extent of the horizon or layer is described.

Code	Meaning	Description
VF	Very few	Occupies < 5 percent
F	Few	Occupies 5 to 25 percent
C	Common	Occupies 25 to 50 percent
M	Many	Occupies > 50 percent

Table E.25. *Surface features abundance codes.*

Distinctness

Distinctness refers to the ease and degree of certainty with which a surface feature can be identified.

Code	Meaning	Description
F	Faint	Evident only on close examination with 10X magnification and cannot be identified positively in all places without greater magnification. The contrast with the adjacent material in color, texture, and other properties is small.
D	Distinct	Can be detected without magnification, although magnification or tests may be needed for positive identification. The feature contrasts enough with the adjacent material to make a difference in color, texture, or other properties evident.
P	Prominent	Conspicuous without magnification when compared with a surface broken through the soil. Color, texture, or some other property or combination of properties contrasts sharply with properties of the adjacent material or the feature is thick enough to be conspicuous.

Table E.26. *Distinctness class codes.*

Location of Surface Features

Type of feature	Code	Meaning
Surface features	SC	Root channels
Surface features	PLB	Plate bottoms
Surface features	BG	Between sand grains
Surface features	VF	Ped vertical faces
Surface features	CC	Concretions
Surface features	PF	All ped faces
Surface features	PEPO	Peds and pores
Surface features	HF	Ped horizontal faces
Surface features	BF	Ped lower surface (bottom faces)
Surface features	BR	Rock lower surface
Surface features	NO	Nodules
Surface features	RF	Rock fragments
Surface features	SGR	Sand and gravel
Surface features	TC	Column tops
Surface features	TF	On top faces of peds
Surface features	TR	Rock upper surface
Surface features	SP	On surfaces along pores

Table E.27. *Surface feature location codes.*

The order of the description of surface features is usually amount, distinctness, color, kind, and location. For example: “few distinct grayish brown (10YR 5/2) clay films/clay skins on vertical faces of peds”; “many distinct brown clay bridges between mineral grains.”

Rock Fragments and Roots

Field Name	Description and Action To Be Taken
Rock Fragments	Using the ocular method and/or line intercept method, determine the percent of gravels (GR), cobbles (CB), stones (ST), and boulders (BY) for each horizon.
Roots	Quantity, size, and location of roots in each layer are recorded (USDA NRCS 1993, 184-188). Using features of the roots (length, flattening, nodulation and lesions), the relationships to special soil attributes or to structure may be recorded as notes. Quantity of roots is described in terms of numbers of each size per unit area. The class placement for quantity of roots pertains to an area in a horizontal plane unless otherwise stated. This unit area changes with root size as follows: 1 cm² for very fine and fine, 1 dm² for medium and coarse and 1 m² for very coarse. The quantity classes given in table E.28.

Code	Meaning	Description
F	Few	< 1 per unit area
C	Common	1–5 per unit area
M	Many	> 5 per unit area

Table E.28. *Quantity of roots codes.*

Roots are described in terms of a specified diameter size.

Code	Meaning	Description
VF	Very fine	< 1 mm
F	Fine	1–2 mm
M	Medium	2–5 mm
C	Coarse	5–10 mm
VC	Very coarse	> 10 mm

Table E.29. *Size of roots codes.*

Pores

Field Name	Description and Action To Be Taken
Pores	Pore space is a general term for voids in the soil material (USDA NRCS 1993, 186-190). The term includes matrix, nonmatrix, and interstructural pore space. Matrix pores are formed by the agencies that control the packing of the primary soil particles. These pores are usually smaller than nonmatrix pores. In addition, their aggregate volume and size would change markedly with water state for soil horizons or layers with high extensibility. Nonmatrix pores are relatively large voids that are expected to be present when the soil is moderately moist or wetter, as well as under drier states. The voids are not bounded by the planes that delimit structural units. Interstructural pores, in turn, are delimited by structural units. Inferences as to the interstructural porosity may be obtained from the structure description. Commonly, interstructural pores are at least crudely planar. Nonmatrix pores may be formed by roots, animals, action of compressed air, and other agents. Most nonmatrix pores are either vesicular (approximately spherical or elliptical) or tubular (approximately cylindrical and elongated). Some are irregularly shaped. Nonmatrix pores are described by quantity, size, shape, and vertical continuity—generally in that order. Some examples of descriptions of pores are “many fine tubular pores,” “few fine tubular pores and many medium tubular pores with moderate vertical continuity,” and “many medium vesicular pores in a horizontal band about 1-cm wide at the bottom of the horizon.”

Quantity classes pertain to numbers per unit area: 1 cm² for very fine and fine pores, 1 dm² for medium and coarse pores, and 1 m² for very coarse.

Code	Meaning	Description
F	Few	< 1 per unit area
C	Common	1–5 per unit area
M	Many	> 5 per unit area

Table E.30. *Quantity of pores codes.*

Pores are described in five classes relative to a specified diameter size.

Code	Meaning	Description
VF	Very fine	< 0.5 mm
F	Fine	0.5–2.0 mm
M	Medium	2.0–5.0 mm
C	Coarse	5.0–10.0 mm
VC	Very coarse	> 10.0 mm

Table E.31. *Size of pores codes.*

Pores are described in five classes relative to their shape.

Code	Meaning	Description
VE	Vesicular	Approximately spherical or elliptical
DT	Dendritic Tubular	Cylindrical, elongated, branching voids
TU	Tubular	Approximately cylindrical and elongated
IR	Interstitial	Irregularly shaped
IG	Irregular	Nonconnected cavities, chambers

Table E.32. *Shape of pores codes.*

Effervescence

Field Name	Description and Action To Be Taken
Effervescence Class	Cold 2.87N (about 1:10 dilution of concentrated HCL) hydrochloric acid is used to test for carbonates in the field. The amount and expression of effervescence is affected by size distribution and mineralogy as well as the amount of carbonates. Consequently, effervescence cannot be used to estimate the amount of carbonate.

Code	Meaning	Description
NE	Noneffervescent	No reaction.
VS	Very slightly effervescent	Few bubbles seen.
SL	Slightly effervescent	Bubbles readily seen.
ST	Strongly effervescent	Bubbles form low foam.
VE	Violently effervescent	Thick foam forms quickly.

Table E.33. *Effervescence class codes.*

Water State

Field Name	Description and Action To Be Taken
PH	Enter the pH value. List reagent or method used in notes section.
Water State Class	Three classes defined below are used in this field. See discussion on pages 90 to 98 of the <i>Soil Survey Manual</i> (USDA NRCS 1993) for further definitions of classes.

Code	Meaning
D	Dry
M	Moist
W	Wet

Table E.34. *Water state class codes.*

Accessory Properties

Masses, plinthite, nodules, concretions, crystals, ironstone, pressure faces, and slickensides (USDA NRCS 1993, 169-172) are accessory properties of soils. These features are identifiable bodies within the soil that were formed by pedogenesis. Some of these bodies are thin and sheetlike, some are nearly equidimensional, and others have irregular shapes. They may contrast sharply with the surrounding material in strength, composition, or internal organization. Alternatively, the differences from the surrounding material may be slight. Soft rock fragments, which have rock structure but are weakly cemented or noncemented, are not considered concentrations. They are excluded based on inference as to a geological as opposed to pedological origin.

Masses are noncemented concentrations of substances that commonly cannot be removed from the soil as a discrete unit. Most accumulations consist of calcium carbonate, fine crystals of gypsum or more soluble salts, or iron and manganese oxides. Except for very unusual conditions, masses have formed in place.

Plinthite consists of reddish, iron-enriched bodies that are low in organic matter and are coherent enough to be separated readily from the surrounding soil. Plinthite commonly occurs within and above reticulately mottled horizons. Soil layers that contain plinthite rarely become dry in the natural setting. The bodies are commonly about 5 to 20 mm across their smallest dimension. Plinthite bodies are firm or very firm when moist, hard, or very hard when air dry, and become moderately cemented on repetitive wetting and drying.

Nodules and concretions are cemented bodies that can be removed from the soil intact. Composition ranges from material dominantly like that of the surrounding soil to nearly pure chemical substances entirely different from the surrounding material. Their form is apparently not governed by crystal forms based on examination at a magnification of 10X, as is the case for crystals and clusters of crystals. It is impossible to be sure if some nodules and concretions formed where they are observed or were transported.

Type of feature	Code	Meaning
Concentrations	BAM	Barite masses
Concentrations	BAX	Barite crystals
Concentrations	BC	Biological concentrations (undifferentiated)
Concentrations	CAC	Carbonate concretions
Concentrations	CAM	Carbonate masses
Concentrations	CAN	Carbonate nodules
Concentrations	CAX	Calcite crystals
Concentrations	CBM	Clay bodies
Concentrations	CCD	Dark concretions

Type of feature	Code	Meaning
Concentrations	CCIM	Iron-manganese concretions
Concentrations	CCIR	Iron concretions
Concentrations	CCMN	Manganese concretions
Concentrations	CO	Concentrations (undifferentiated)
Concentrations	COLI	Lime concretions
Concentrations	CR	Crystals (undifferentiated)
Concentrations	DIB	Diatoms
Concentrations	DM	Finely disseminated materials (undifferentiated)
Concentrations	DNN	Durinodes
Concentrations	DPC	Clay depletions
Concentrations	DPIR	Iron depletions
Concentrations	FDC	Finely disseminated carbonates
Concentrations	FDS	Finely disseminated salts
Concentrations	FPB	Fecal pellets
Concentrations	GBC	Gibbsite concretions
Concentrations	GBN	Gibbsite nodules
Concentrations	GLI	Glauconite pellets
Concentrations	GNM	Nests of gypsum
Concentrations	GYM	Masses of gypsum
Concentrations	GYX	Gypsum crystals
Concentrations	HACR	Halite crystals
Concentrations	ICB	Insect casts
Concentrations	MA	Masses (undifferentiated)
Concentrations	MIC	Mica flakes
Concentrations	MSD	Masses of dark accumulations
Concentrations	MSIM	Masses of iron-manganese
Concentrations	MSIR	Masses of iron
Concentrations	MSL	Masses of lime
Concentrations	MSMN	Masses of manganese
Concentrations	MSOX	Masses of oxides
Concentrations	NO	Nodules (undifferentiated)
Concentrations	NOD	Dark nodules
Concentrations	NOIM	Iron-manganese nodules
Concentrations	NOIR	Ironstone nodules
Concentrations	NOLI	Lime nodules
Concentrations	NOMN	Manganese nodules
Concentrations	OPN	Opal
Concentrations	PPB	Plant phytoliths
Concentrations	RSB	Root sheaths
Concentrations	SAM	Masses of salt

Type of feature	Code	Meaning
Concentrations	SAX	Salt crystals
Concentrations	SFB	Shell fragments
Concentrations	SGPT	Plinthite segregations
Concentrations	SHMG	Magnetic shot
Concentrations	SHNMG	Nonmagnetic shot
Concentrations	SIC	Silica concretions
Concentrations	SIM	Masses of silica
Concentrations	SSB	Sponge spicules
Concentrations	THCB	Carbonate threads
Concentrations	THGP	Gypsum threads
Concentrations	TIC	Titanium oxide
Concentrations	WCB	Worm casts
Concentrations	WNO	Worm nodules

Table E.35. *Concentration kind codes.*

Soft Masses and Concretions

Code	Meaning	Description
F	Few	Less than 2 percent of the surface area
C	Common	2 to 20 percent of the surface area
M	Many	More than 20 percent of the surface area

Table E.36. *Abundance codes.*

Code	Meaning	Description
F	Fine	< 2 mm
M	Medium	2–5 mm
C	Coarse	5–20 mm
VC	Very coarse	20–76 mm
EC	Extremely coarse	> 76 mm

Table E.37. *Size codes.*

Code	Meaning	Description
R	Rounded	Generally rounded or slightly oblong.
C	Cylindrical	Cylindrical or tubular; one dimension is much greater than the other two.
P	Platelike	Shaped crudely like a plate; one dimension is very much smaller than the other two.
I	Irregular	Characterized by branching, convoluted, or mycelial form.

Table E.38. *Shape codes.*

Type of feature	Code	Meaning
Concentrations	ARF	Around rock fragments
Concentrations	TOH	Top of horizon
Concentrations	CRK	Cracks
Concentrations	MPF	Matrix
Concentrations	DIA	Diatoms
Concentrations	MAT	Matrix adjacent to pores
Concentrations	ALS	Along lamina or strata surfaces
Concentrations	RPO	On surfaces along root channels
Concentrations	SSS	On slickensides
Concentrations	MAC	Matrix surrounding concentrations
Concentrations	MAD	Matrix surrounding depletions
Concentrations	LPO	Pore lining
Concentrations	APF	Ped faces
Concentrations	HPF	Ped horizontal faces
Concentrations	PFPO	Ped faces and pores
Concentrations	VPF	Ped vertical faces
Concentrations	TOT	Throughout
Concentrations	BPF	Between peds
Concentrations	BRF	On bottom of rock fragments
Concentrations	SPO	On surface along pores
Concentrations	MPO	Infused into the matrix adjacent to pores (hypocoats)

Table E.39. *Concentration location codes.*

Excavation Difficulty

Field Name	Description and Action To Be Taken
Excavation Difficulty	Enter the appropriate code from table E.40 for excavation difficulty.

Code	Classes	Test Description
LO	Low	Can be excavated with a spade using arm-applied pressure only. Neither application of impact energy nor application of pressure with the foot to a spade is necessary.
MO	Moderate	Arm-applied pressure to a spade is insufficient. Excavation can be accomplished quite easily by application of impact energy with a spade or by foot pressure on a spade.
HI	High	Excavation with a spade can be accomplished, but with difficulty. Excavation is easily possible with a full length pick using an over-the-head swing.

Code	Classes	Test Description
VH	Very high	Excavation with a full-length pick using an over-the-head swing is moderately to markedly difficult. Excavation is possible in a reasonable period of time with a backhoe mounted on a 40 to 60 kW (50 to 80 hp) tractor.
EH	Extremely high	Excavation is nearly impossible with a full-length pick using an over-the-head arm swing. Excavation cannot be accomplished in a reasonable time period with a backhoe mounted on a 40 to 60 kW (50 to 80 hp) tractor.

Table E.40. *Excavation difficulty codes.*

Appendix F. TEUI Documentation

The following examples were adapted from the *Bridger-East Ecological Unit Inventory* (Svalberg et al. 1997).

Ecological Type Description

PIAL/VASC, Ivywild Family Ecological Type

Whitebark pine/grouse whortleberry, Ivywild Family Ecological Type

Concept and Distribution

This ecological type (ET) consists of the PIAL/VASC Plant Association (p.a.) on soils of the Ivywild Family. The PIAL/VASC p.a. includes plant communities in which white-bark pine is the projected climax dominant tree and the understory is characterized by grouse whortleberry. Soils of the Ivywild Family are 20 to 40 inches deep, well drained, and have a loamy-skeletal subsoil layer.

This ET occurs dominantly from Doubletop Mountain south to Big Sandy Opening within the Subsummit Uplands Subsection. It is a component of map units 2345, 2601, and 2602. The geographic extent of this ET is approximately 53,480 acres. Within this area, it occupies about 9,590 acres.

Geomorphology

Landscape: Mountains.

Landforms: Roche Mountonee-Alpine Glaciation – Ice Erosion-Glacial.

Common Landforms: Bench and Freeface.

Landscape Position: Backslopes and sideslopes.

Surficial/Parent Materials

Primary Lithology: Unconsolidated.

Secondary Lithology: Glacial till desposit, colluvium, and residuum. Colluvium, residuum, and glacial till are derived from Early to Late Archean granite, granite gneiss, and granodiorite.

Colluvium occurs predominantly as slopewash, with some areas of talus and scree deposits. Glacial till is dominantly Late Wisconsin (Pinedale) age. Higher elevations may have Holocene (Neoglacial) till present.

Parent/Surficial Material Size Class: Bouldery.

Bedrock

Primary Lithology: Igneous Intrusive, Metamorphic.

Secondary Lithology: Granite, granodiorite, gneiss. Bedrock includes some areas of diorite, quartz diorite, amphibolite, and/or quartzite.

Climate: Cryic temperature regime and ustic moisture regime. Estimated mean annual precipitation ranges from 21 to 46 inches.

Elevation: Full Range: 9,000 to 10,800 feet. Typical Range: 9,000 to 10,500 feet.

Slope: 5 to 50 percent, on all aspects.

Potential Natural Vegetation: The potential natural vegetation of this ET is the PIAL/VASC p.a. (Steele et al. 1983).

In mature stands, total tree canopy cover ranges from 10 to 30 percent. Whitebark pine is the projected climax dominant tree. Lodgepole pine is the major early seral species. At lower elevations, lodgepole pine may persist for long periods of time and act as a codominant (Steele et al. 1983).

Shrub cover ranges from 10 to 30 percent. Grouse whortleberry is the climax dominant. It forms a low, somewhat open mat approximately 6 inches high. Planeleaf willow may be found on sites transitional to wetter areas.

Herbaceous cover is usually sparse and ranges from 5 to 30 percent. The most common graminoids are Wheeler's bluegrass, Ross' sedge, and spike trisetum. Common forbs include pussytoes, heartleaf arnica, and varileaf cinquefoil. Herbs that increase with disturbance are fireweed, pussytoes, western yarrow, and common dandelion.

Soil Description: Soils of this ET are 20 to 40 inches deep, well drained, and have a permeability of 2.0 to 6.0 inches per hour. Available water capacity to a depth of bedrock ranges from 1.5 to 2.4 inches.

Soil Name: Ivywild Family.

Taxonomic Classification: Loamy-skeletal, mixed, superactive Typic Dystrocryepts.

Location of Typical Pedon: Horseshoe Lake quadrangle, SW 1/4 of NW 1/4 Section 03, T. 34 N., R. 107 W., 1 mile east of Belford Lake, Pinedale Ranger District, Sublette County, Wyoming. Latitude 42 56' 39" N., Longitude 109 37' 16" W. Map unit 2602. Reference pedon: L1804B.

Horizon Description

- A 0 to 5 inches; dark grayish brown (10YR 4/2) very bouldery sandy loam, very dark grayish brown (10YR 3/2) moist; weak fine granular structure; soft, very friable, nonsticky and nonplastic; 5 percent gravel, 5 percent cobbles, 5 percent stones, 20 percent boulders; many very fine, few fine, many medium, few coarse roots; many very fine and fine, common medium interstitial pores; pH 6.0; clear smooth boundary.
- Bw1 5 to 12 inches; yellowish brown (10YR 5/4) very bouldery sandy loam, dark yellowish brown (10YR 4/4) moist; weak fine and medium subangular blocky structure; soft, very friable, nonsticky and nonplastic; 20 percent gravel, 15 percent cobbles, 10 percent stones, 10 percent boulders; many very fine, few fine, many medium roots; common very fine, few fine interstitial pores; pH 6.0; gradual smooth boundary.
- Bw2 12 to 30 inches; yellowish brown (10YR 5/4) very stony sandy loam, dark yellowish brown (10YR 4/4) moist; weak fine subangular blocky structure; soft, friable, nonsticky and nonplastic; 20 percent gravel, 15 percent cobbles, 10 percent stones, 5 percent boulders; few very fine roots; common very fine and fine interstitial pores; pH 6.0; abrupt wavy boundary.
- R 30 inches; granitic bedrock.

Observed Characteristics: Depth to hard bedrock ranges from 22 to 36 inches. Rooting depth ranges from 12 to 31 inches. Texture of the A horizon is very bouldery sandy loam, very stony sandy loam, or cobbly loam. The A horizon is 5 to 10 percent gravel, 2 to 15 percent cobbles, 3 to 20 percent stones, and 5 to 20 percent boulders. The pH of the A horizon ranges from 5.0 to 6.0. Texture of the Bw horizons is very bouldery sandy loam, very stony sandy loam, or very cobbly sandy loam. The Bw horizons are 15 to 20 percent gravel, 10 to 15 percent cobbles, 5 to 20 percent stones, and 5 to 10 percent boulders. The pH of the Bw horizons ranges from 4.5 to 6.0. A C horizon with a texture of very stony sandy loam, extremely bouldery sandy loam, or very gravelly sandy loam is present in some pedons.

Plant Community Composition (n=5)

Common Name	Code	Const.	Cover	Const.	Cover	Ecological Role
<u>Overstory</u>						
Trees						
Whitebark pine	PIAL	100	6	100	18	Major climax dominant
Tall lodgepole pine	PICOL	20	2	20	8	Incidental to minor seral
<u>Understory</u>						
Shrubs:						
Grouse whortleberry	VASC	80	18			Major climax increaser, resprouts after fire
Alpine prickly currant	RIMO2	20	3			Minor climax increaser
Perennial grasses						
Wheeler's bluegrass	PONE	100	5			Minor climax decreaser, rhizomatous
Spike trisetum	TRSP2	60	2			Minor climax decreaser
Slender bluegrass	POGR	20	1			Minor climax
Sandberg bluegrass	POSEI	20	1			Minor climax
Sedges and rushes						
Ross' sedge	CARO5	40	4			Minor climax, increases fire, grazing, or mechanical disturbance
Parry's rush	JUPA	40	3			Minor climax increaser
Sedge	CAREX	20	1			Minor climax
Rush	JUNCU	20	1			Minor climax
Perennial forbs						
Pussytoes	ANTEN	100	1			Minor climax, increases on bared soil
Heartleaf arnica	ARCO9	80	2			Minor climax increaser, rhizomatous
Varileaf cinquefoil	PODI2	60	1			Minor climax increaser
Aster	ASTER	40	2			Minor climax increaser, often rhizomatous
Western yarrow	ACMIL3	40	1			Minor climax increaser
Fireweed	EPAN2	40	1			Seral, increases after fire
Lupine	LUPIN	20	6			Seral increaser

Common Name	Code	Const.	Cover	Const.	Cover	Ecological Role
Pale agoseris	AGGL	20	3			Minor climax decreaser
Rydberg's arnica	ARRY	20	3			Minor climax increaser, rhizomatous
Manyray goldenrod	SOMUS	20	2			Minor climax increaser
Sulphur buckwheat	ERUM	20	1			Minor climax, increases on bared soil
Fleabane	ERIGE2	20	1			Minor climax increaser
Ballhead sandwort	ARCO5	20	1			Minor climax, increases on bared soil

Const. = Constancy, the percentage of plots in which a species is present.

Cover = The mean cover of a species for the plots in which it is present.

Similar Ecological Types

The PIAL/VASC, Ivywild Family ET is similar to other ETs on Ivywild Family soils.

No other ETs have been defined with the PIAL/VASC p.a. Other ETs on Ivywild

Family soils differ from the PIAL/VASC, Ivywild Family ET as follows:

The ABLA-PIEN/VASC, Ivywild Family has (1) Subalpine fir or Engelmann spruce as the climax dominant tree, and (2) no lodgepole pine.

The ABLA/ARCO9, Ivywild Family has (1) Subalpine fir as the climax dominant tree, (2) lower elevations, and (3) an understory represented by heartleag arnica.

The ABLA/VASC, Ivywild Family has (1) subalpine fir as the climax dominant tree, and (2) lower elevations.

Associated Ecological Types

The PIAL/VASC, Ivywild Family ET is associated primarily with ETs within the ABLA/VASC p.a. and the ABLA/PIEN/VASC group with well drained, loamy-skeletal soils. It is also an association with rock outcrop. The table below lists the ETs that occur as map unit components within the geographic extent of this ET and the area in which each is associated with this ET.

Associated Ecological Types	Acres	Percent Co-occurrence
Rock Outcrop	44,696	84%
ABLA/VASC, Jeru Family ET	30,820	58%
ABLA-PIEN/VASC, Ivywild Family ET	13,876	26%
ABLA-PIEN/VASC, Boze Family ET	8,784	16%
DECE, Oxyaquic Cryumbrepts, C-L Family, D, MW ET	8,784	16%

Map Unit Description

MAP UNIT: 2345

Subsummit Moraines, Spruce/Fir – Whitebark Pine – Meadow Complex

MAP UNIT COMPOSITION

This map unit is a mosaic of coniferous forests and meadows on benches, roche moutonnées, ground moraines, and benches. The ABLA-PIEN/VASC, Boze Family ET occurs on benches and roche moutonnées and mountain slopes. The PIAL/VASC, Ivywild Family ET occurs on similar landforms with southerly aspects. The DECE, Oxyaquic Dystrocryepts, C-L Family, D, MW ET occurs on lower backslopes, footslopes, and toeslopes of ground moraines.

35 Percent – ABLA-PIEN/VASC (subalpine fir – Engelmann spruce/grouse whortleberry), Boze Family ET

25 Percent – PIAL/VASC (whitebark pine/grouse whortleberry), Ivywild Family ET

25 Percent – DECE (tufted hairgrass), Oxyaquic Dystrocryepts, C-L Family, D, MW ET

15 Percent – Minor Components

SETTING

Hierarchy of Ecological Units: The Subsummit Uplands Subsection.

General Location: Sandpoint Lake south to Poston Lake.

Elevation: Full Range: 9,500 to 10,800 feet
80 Percent Range: 9,600 to 10,400 feet
Annual Precipitation: 29 to 36 inches
Areal Extent: 8,800 acres

Slope: 0 to 25 percent

Aspect: Dominantly southwest, minor east, northwest, and flat

COMPONENT DESCRIPTIONS

ABLA-PIEN/VASC, Boze Family ET Component

Potential Natural Vegetation: ABLA-PIEN/VASC group. This includes plant communities in which either subalpine fir or Engelmann spruce dominate at climax and the understory is dominated by grouse whortleberry. The ABLA-PIEN/VASC group is not expected to occur below 9,700 feet. Below this elevation, the ABLA/VASC.p.a. is expected to occur.

Landform: Roche moutonnées, benches, and ground moraines on glacial mountain slopes.

Primary Lithology: Unconsolidated.

Secondary Lithology: Glacial till desposit, colluvium, and residuum. Colluvium, residuum, and glacial till are derived from Early to Late Archean granite, granite gneiss, and granodiorite.

Colluvium occurs predominantly as slopewash, with some areas of talus and scree deposits. Glacial till is dominantly Late Wisconsin (Pinedale) age. Higher elevations may have Holocene (Neoglacial) till present.

Parent/Surficial Material Size Class: Bouldery.

Bedrock

Primary Lithology: Igneous Intrusive, Metamorphic

Secondary Lithology: Granite, granodiorite, gneiss. Bedrock includes some areas of diorite, quartz diorite, amphibolite, and/or quartzite.

Soil Name: Boze Family.

Classification: Coarse-loamy, mixed, superactive Oxyaquic Dystrocryepts.

Landform Position: bench.

Depth: 28 inches to a dense layer, and more than 40 inches to bedrock.

Drainage Class: Well drained.

Permeability: 0.6 to 2.0 inches per hour.

Available Water Capacity (AWC): 2.6 inches to dense layer.

Reference Pedon: O2302B.

PIAL/VASC, Ivywild Family ET Component

Potential Natural Vegetation: PIAL/VASC p.a. This includes plant communities in which whitebark pine is the climax dominant tree and the understory is dominated by grouse whortleberry.

Landform: Roche moutonnées, benches, and ground moraines on glacial mountain slopes.

Primary Lithology: Unconsolidated.

Secondary Lithology: Glacial till desposit, colluvium, and residuum. Colluvium, residuum, and glacial till are derived from Early to Late Archean granite, granite gneiss, and granodiorite.

Colluvium occurs predominantly as slopewash, with some areas of talus and scree deposits. Glacial till is dominantly Late Wisconsin (Pinedale) age. Higher elevations may have Holocene (Neoglacial) till present.

Parent/Surficial Material Size Class: Bouldery

Bedrock

Primary Lithology: Igneous Intrusive, Metamorphic.

Secondary Lithology: Granite, granodiorite, gneiss. Bedrock includes some areas of diorite, quartz diorite, amphibolite, and/or quartzite.

Soil Name: Ivywild Family.

Classification: Loamy-skeletal, mixed, superactive Typic Dystrocryepts.

Landscape Position: Narrow bench.

Depth: 31 inches.

Drainage Class: Well drained.

Permeability: 2.0 to 6.0 inches per hour.

Available Water Capacity (AWC): 1.6 inches.

Reference Pedon: O2109B.

DECE, Oxyaquic Dystrocryepts, C-L Family, D, MW ET Component

Potential Natural Vegetation: DECE community type (c.t.) This includes herbaceous riparian communities characterized by tufted hairgrass.

Landform: Roche moutonnées, benches, and ground moraines on glacial mountain slopes.

Primary Lithology: Unconsolidated.

Secondary Lithology: Glacial till desposit, colluvium, and residuum. Colluvium, residuum, and glacial till are derived from Early to Late Archean granite, granite gneiss, and granodiorite.

Colluvium occurs predominantly as slopewash, with some areas of talus and scree deposits. Glacial till is dominantly Late Wisconsin (Pinedale) age. Higher elevations may have Holocene (Neoglacial) till present.

Parent/Surficial Material Size Class: Bouldery.

Bedrock

Primary Lithology: Igneous Intrusive, Metamorphic.

Secondary Lithology: Granite, granodiorite, gneiss. Bedrock includes some areas of diorite, quartz diorite, amphibolite, and/or quartzite.

Soil Name: Oxyaquic Dystrocryepts, C-L Family, D, MW.

Classification: Coarse-loamy, mixed, superactive Oxyaquic Cryumbrepts.

Landscape Position: Toeslope.

Depth: More than 40 inches.

Drainage Class: Moderately well drained.

Permeability: 2.0 to 6.0 inches per hour.

Available Water Capacity (AWC): 3.3 inches.

Depth to Seasonal High Water Table: 21 inches.

Reference Pedon: Q2309B.

Minor Components

Rock outcrop.

The ABLA-PIEN/VASC (subalpine fir-Engelmann spruce/grouse whortleberry) group on soils similar to the Boze Family, except with a greater percentage of rock fragments in the subsoil.

The PIAL/VASC (whitebark pine/grouse whortleberry) p.a. on soils similar to the Ivywild Family, except with a thicker and/or darker surface layer.

The DECE (tufted hairgrass) c.t. on soils that are less than 40 inches deep to bedrock or a dense layer.

Areas of sedges on wet soils.

Appendix I. Personnel Requirements

Terrestrial Ecological Unit Inventory Specialist Job Description

Ecologist, GS-408-11

Soil Scientist, GS-470-11

Geologist, GS-880-11

Introduction

This position is located at a Terrestrial Ecological Unit Inventory (TEUI) Center. The incumbent serves as a technical expert in soils, ecology, geology, and related disciplines for the Inventory Center, and develops the TEUI on one to four national forests.

Incumbent will also ensure that the development of the TEUI is consistent with the *TEUI Technical Guide*. Incumbent works with the forest(s) in developing management interpretations and applications for the TEUI information.

Major Duties

1. Supplies all land surface (soils, geology, potential natural vegetation, and landform) information to the TEUI, including both photo interpreting and field verifying information on landform, soil, potential natural vegetation, and geology/parent material.
2. Conducts ecological inventory of soil, vegetation, and other environmental components of TEUI from which an ecological classification and mapping system is developed to produce useful land management and planning information. This activity requires intensive field sampling, mapping, and computerized analysis. The classifications of the TEUI and mapping information are used for indexing ecological information, inventory, data storage, and retrieval. Provides technical expertise in managing and analyzing this information, including entering and managing digital data in a Geographic Information System (GIS) environment.
3. Keeps abreast of the latest information relative to soil taxonomy, ecological classifications (including plant associations and integrated landform classifications), models, and evaluation methods to ensure adoption and application of new technology and theories.
4. Ensures consistency and quality of the TEUI. Focuses on the timeline of the inventory, ensuring completion of the workplan. Takes corrective action to ensure that policies,

plans, and prescribed budget are followed within predetermined flexibility limitations. Participates in quality control reviews as well as general management reviews of the inventory.

5. Works to integrate aquatic information and existing vegetation into inventory design and, where possible, polygon structure or appropriate modeling techniques. Establishes and maintains an atmosphere of complete cooperation with forest and District soil, ecology, and geology specialists. Cooperates with the Regional Office in the further refinement of inventory procedures. Formulates and recommends changes to the *TEUI Technical Guide*. Coordinates with other Inventory Centers around the Region to assure consistency and quality be maintained on a Regionwide basis.
6. Responsible for working with forest and District specialists to develop interpretations and applications of the TEUI information for land management planning and ecosystem management.

Factor 1. Knowledge Required by the Position

Professional knowledge and experience in soil classification, soil mapping, soil correlation, development of report interpretations, and report writing, which are used in completing soil resource inventories.

Professional knowledge and experience in plant association classification, and potential natural vegetation mapping and modeling. Development of report interpretations and report writing, which are used in completing plant association classification and resource inventories.

Mastery of advance concepts, principles, and practices of natural resources, databases, and the GIS environment sufficient to conduct an inventory based on the integration of ecosystem elements. Good working knowledge of related fields, such as hydrology, forestry, engineering, wildlife, fisheries, and ecology to coordinate ecological relationships.

Initiative and creativity in developing new approaches, methodologies, and techniques to meet target demands with limited funding and personnel ceilings.

Factor 2. Supervisory Controls

The Inventory Center leader will be the immediate supervisor and will provide administrative leadership and guidance in significant policy matters and coordination on a Regionwide basis. Functions with independence in reaching decisions. The incumbent clears with the supervisor approaches that have potential policy impacts. Results are

reviewed by the supervisor and the Regional Office TEUI Coordinator. Performance is determined by these results.

Factor 3. Guidelines

The basic guides are the broad policies and objectives of the Forest Service and the broad policies of the National Cooperative Soil Survey as contained in the *National Soil Survey Handbook* (USDA NRCS 2003b) and the *Soil Survey Manual* (USDA NRCS 1993). Regional Guides, forest plans, applicable regulations, recognized standards, and administrative knowledge and training act as day-to-day guidelines.

Sound professional judgment, ingenuity, and resourcefulness are required. The incumbent will follow the *TEUI Technical Guide*. Many different situations will be encountered. Incumbent is expected to assist in developing new methods and procedures, to identify the latest technical concepts and practices, and to incorporate them in the inventory procedures.

Factor 4. Complexity

The assignment requires sound professional knowledge of plant and soil interactions, soil series, and plant associations. Must have a basic understanding of geology, geomorphology, climate, and vegetative characteristics. The assignment includes analysis of an extremely complex interaction of abiotic factors and flora along with cooperating with the Districts, forests, Regional Office, and other Inventory Centers.

The work assignment will require the incumbent to relate new work situations to precedent situations, to extend or modify existing techniques, and to adequately solve problems. Incumbent will work with the forests to develop management interpretations and applications for the information. Occasionally, the assignments require substantial effort to overcome resistance to change when it is necessary to modify an accepted method or approach.

Factor 5. Scope and Effect

The work associated with this position is primarily to carry out the complete classification and inventory of landforms, soils, potential natural vegetation, and geology/parent material on one to four national forests. The results of this work will have a significant effect on preparing the forests for a GIS and ecosystem management.

Factor 6. Personal Contacts

Contacts help develop new ideas and procedures, validate existing procedures, and complete the development, testing, and implementation of the TEUI on one to four forests and within the Region.

Factor 7. Purpose of Contacts

Contacts help develop new ideas and procedures, validate existing procedures, and complete the development, testing, and implementation of the TEUI on one to four forests and within the Region.

Factor 8. Physical Demands

Demands range from sedentary work seated in an office using stereoscopes to the rigorous physical exertion of walking in rugged terrain and streams. Physical exertion will include hiking, climbing, riding horses, and driving all-wheel vehicles over unimproved roads.

Factor 9. Work Environment

Routine office work is performed in a normal office setting. Work requires exposure to some risks involved in logging operations, firefighting, and walking or riding in isolated country, sometimes in adverse weather conditions. Safety precautions are required and the employee must wear protective equipment while making on-the-ground inspections.

San Diego, Calif., NHAP color infrared, original scale: 1:58,000, February 1985.

Aerial Photographs and Satellite Images

Photographs and other images of the Earth taken from the air or from space afford valuable information about the planet; its landforms, vegetation, and resources. Aerial and satellite images permit researchers to see and accurately map patterns of land use that otherwise are not readily visible from the ground. Transient phenomena such as ocean currents or pollution discharges can be studied. The aerial perspective allows us to see landscape features on regional, continental, or even global scale.

Bayou Laforche, La., NAPP, color infrared, original scale: 1:40,000, October 1990.

The U.S. Geological Survey and Remote Sensing

Because photographs and images taken from the air or from space are acquired without direct contact with the ground, they are referred to as remotely sensed images. The U.S. Geological Survey (USGS) has used remote sensing from the early years of the 20th century to support earth science studies and for mapping purposes.

The USGS began using aerial photographs for mapping in the 1930's. Successive aerial photographs can be overlapped, and using a

Horseshoe Falls (Niagara Falls), N.Y. and Canada, looking South, low oblique (scale will vary), EPA, July 1989.

stereoscope, can be made into contour maps. Although aerial photographs from earlier decades are scarce, the USGS archives photographs from its mapping projects and from national programs.

Photographs and some images from U.S. space programs such as the Landsat program, begun in 1972, are also held by the USGS. Most Landsat scenes can only be obtained in digital form for use in computer-based image processing and geographic information systems or as film positives or negatives.

This booklet discusses some characteristics of aerial photographs and satellite images and the types of images that are available from the USGS.

How Images Are Classified

Images taken from above the Earth are usually categorized according to the altitude of the aircraft or spacecraft, the type of image medium, and the type and characteristics of the sensor.

Altitude

Manned or unmanned spacecraft usually collect images from altitudes greater than 150 miles. Aircraft commonly operate at altitudes from 5,000 to 60,000 feet. The height from which a photograph or image is taken and the physical characteristics of the sensor, including the focal length, largely determine the area covered and the amount of detail shown in a remotely sensed image. In general, the level of detail is the greatest in low-altitude photographs that cover relatively small areas. Satellite images cover larger areas but show less detail.

Views of the same area from progressively higher altitudes

E-1702-99CT

Image media

Aerial photographs are produced by exposing film, an image medium, directly to solar energy reflected from the Earth. Photographic film has been used for aerial reconnaissance, for both military and civilian purposes, since the middle of the 1860's. Black-and-white film was used at first; color film became widely used in the 1950's.

Color-infrared film, which records energy from portions of the electromagnetic spectrum invisible to the human eye, was developed to detect camouflaged military installations in the 1940's. In a color-infrared (also known as a false-color) photograph, near-infrared light reflected from the scene will show as red, red will show as green, green as blue, and blue as black. Color-infrared film is useful for distinguishing between healthy and diseased vegetation, for delineating bodies of water, and for penetrating atmospheric haze.

Black-and-white and color-infrared films are used today in both high- and low-altitude aerial photography. Natural-color film is used more rarely.

Sensors

Cameras of various types are used to take aerial photographs. Cameras can be carried on aircraft or on such spacecraft as the space shuttle. Satellites commonly use electronic scanners to record ground scenes in digital, or computer-readable, form. Aircraft can also carry electronic scanners. Sensors can be passive; that is, recording radiation reflected from the Earth, or active, generating their own energy. A camera is passive; so are the sensors used aboard the Landsat satellites. These sensors record reflected energy in the visible, infrared, and thermal portions of the spectrum. Satellite data are displayed as images whose colors resemble color-infrared aerial photographs, but the colors of a given image can be manipulated by computer to enhance landscape features.

Side-looking airborne radar (SLAR) instruments on aircraft or satellites generate their own energy and record the amount of energy reflected back to them from the ground.

Original scale

2x enlargement

Overall size

These images represent the three standard paper print sizes for aerial photographs available from the USGS. The standard contact print size is 9 by 9 inches. Enlargements to 18 by 18 inches (2x), and 36 by 36 inches (4x) can also be ordered. In this scene of Washington, D.C., the 9-inch contact print (upper left) represents the original scale of 1:40,000, where 1 inch on the image represents approximately 3,333 feet on the ground. The 18-inch print (above) represents a 2x enlargement with a scale of 1:20,000, where 1 inch on the image represents approximately 1,666 feet on the ground. The 36-inch print (right) represents a 4x enlargement with a scale of 1:10,000, where 1 inch on the image represents approximately 833 feet.

NAPP Roll 4, Frame 78

4x enlargement

NAPP Roll 511, Frame 159

NAPPW Roll 6365, Frame 36

Golden Gate Bridge, NAPP black and white, original scale: 1:40,000, August 1993.

Aerial Photographs

Various types of aerial photographs are archived by the USGS. Although the USGS has used aerial photographs for many decades, the availability of photographs from the earliest years is limited. Most recent photographs are from national programs and were taken at relatively high altitudes with predominately black-and-white or color-infrared film.

NHAP 82 Roll 261, Frame 130

Golden Gate Bridge, NHAP color infrared, original scale: 1:58,000, August 1982.

National Aerial Photography Program

The National Aerial Photography Program (NAPP) was established in 1987 to coordinate the acquisition of aerial photographs for the United States among Federal and State agencies. NAPP photographs are used for mapping, resource planning, land management, and agricultural monitoring. Taken from aircraft flying nominally at 20,000 feet above the terrain, each NAPP photograph covers about 32 square miles of ground. Black-and-white and color-infrared photographs are available from the NAPP program.

NHAP 82 Roll 252, Frame 58

Golden Gate Bridge, NHAP black and white, original scale: 1:80,000, August 1982.

National High Altitude Photography Program

The National High Altitude Photography Program (NHAP) was a Federal project that preceded NAPP, running from 1978 to 1988. NHAP photographs were taken simultaneously with two cameras, one containing black-and-white film, the other color infrared. The NHAP aircraft flew at 40,000 feet above the terrain. These photographs cover more area, but show less detail, than NAPP photographs. An NHAP black-and-white photograph covers about 129 square miles, and because of the longer focal length in the second camera, an NHAP color-infrared photograph covers about 68 square miles.

Washington, D.C., section of a 1-m resolution, quarter-quadrangle digital orthophoto, date of photography-April 1988. (Reduced 30 percent)

Orthophotos and digital orthophotos

Orthophotos are prepared from perspective aerial photographs or digital representations of these photographs in which the displacements caused by differences in terrain elevations and camera tilt have been removed, giving the orthophoto the geometric characteristics of a map. That is, measurements of distances between points on an orthorectified aerial photograph can be made accurately because of the common scale of the new image. Because aerial photographs show the entire texture of the ground in much greater detail than do conventional line maps, orthophotos are useful for updating maps and in land studies. The USGS produces digital versions of orthophotos for map revision and for computer analysis using geographic information systems.

Aerial photographs from mapping programs

The USGS archives photographs used for making maps that are not associated with national programs. The mapping photographs of some other Federal agencies are also available. Some of these photographs date back to the 1950's. Most show more detail than NAPP and NHAP photographs. These mapping photographs may be in black and white or, in a few cases, in natural color.

Aerial photographs from the National Aeronautics and Space Administration (NASA)

NASA uses aerial photographs for research and to test remote sensing techniques and instruments. These photographs are available in various formats and were taken from altitudes of a few thousand feet up to 60,000 feet, although the majority were collected at the higher altitude. NASA aerial photographs are available in black and white, natural color, or color infrared, but only for certain areas. Digital multispectral scanner data are also available.

Manned spacecraft photographs

Photographs were acquired over limited areas of the Earth on NASA's Gemini (1965-66) and Apollo (1968-1969) missions. Three Skylab missions in 1973 and 1974 provided more than 35,000 photographs.

Astronauts aboard the space shuttle, which began flying in 1981, have taken many photographs of the Earth with hand-held cameras. The photographs from these missions document sites of scientific interest around the world and depict temporary phenomena such as hurricanes and erupting volcanoes. Most of these photographs are in natural color.

Aerial photographs from Government agencies

The Earth Resources Observation Systems (EROS) Data Center of the USGS stores negatives of aerial photographs from other

Federal agencies, including the Bureau of Land Management, the Bureau of Reclamation, the Bureau of Indian Affairs, NASA, and the former Departments of the Army, Navy, and Air Force. Copies of these photographs can be ordered directly from the USGS's Earth Science Information Centers.

Major metropolitan areas of the United States

Color-infrared aerial photographs of the central business districts of more than 100 cities in the United States are available. The photographs are selected largely from the NHAP program, prior to 1987, and were chosen for their high quality. Most of these photographs were taken with color-infrared film at a scale of 1:58,000 (1 inch equals about 0.9 miles or 1 centimeter equals about 0.6 kilometers).

E-1804-99CT

Hurricane Elena, space shuttle photograph over the Gulf of Mexico, September 1985.

Satellite Images

The EROS Data Center processes and stores satellite data from several different types of satellites. The major types are described below.

The Landsat Program

In 1972, the United States launched its first Earth Resources Technology Satellite, ERTS-1, later renamed Landsat 1, for experimental global coverage of the Earth's land masses. Landsats, serially numbered, were launched in 1972, 1975, 1978, 1982, and 1984.

Data are collected by sensors that measure a range of wavelengths of electromagnetic energy reflected or emitted from the Earth. The broad wavelength bands are often from those parts of the electromagnetic spectrum outside the range of human eyesight, showing normally invisible land characteristics. The Landsat data are transmitted to Earth where they are processed by computers and archived.

Global summation of vegetation greenness index for calendar years 1986-1988 (black = low greenness, dark green = high greenness), from AVHRR data, source - NOAA. (Reduced to 87 percent)

Background: Las Vegas, Nev., Landsat 4 TM, April 1983. (Enlarged 420 percent)
E-1469-99CT

E-1884-99CT

Landsats 1-5 have carried versions of a sensor called the multispectral scanner (MSS), which collects data simultaneously from four broad bands of the electromagnetic spectrum, from visible green through near-infrared wavelengths. The MSS images in this booklet have a picture element (pixel) resolution of 79 meters—that is, the height and width of each pixel correspond to 79 meters or about 259 feet on the ground. Landsats 1 and 2 also carried a sensor called the return beam videcon, or RBV, with high geometric accuracy but lower spectral detail than the MSS. Because of technical problems, RBV operations were limited and the sensors were not used on later spacecraft.

The thematic mapper (TM) sensor carried on Landsats 4 and 5, in addition to the MSS, gives higher resolution than the MSS, each pixel corresponding to 30 meters, or about 98 feet on the ground. The TM sensor also records a greater number of bands than the MSS, yielding more detailed spectral information. Landsat images can be processed to emphasize different features of the land, making such data especially useful for scientific studies.

Landsats 4 and 5 pass from north to south over the Equator at an altitude of 705 kilometers (438 miles) each day at about 10 a.m., and their orbits provide repeat coverage of the Earth, allowing the detection of changes. Cloud cover and the need to transmit data directly to a ground station affect the amount of acceptable continuous repeat coverage.

Comparison of Landsat MSS scenes of the Mississippi River Delta, January 16, 1973, and March 3, 1989. (Reduced to 68 percent)

Spectral Sensitivity of Remote Sensing Systems

cm = centimeter
 um = micrometer
 (1 um = 10⁻⁴ cm)
 (1000 um = 0.1 cm)

E-1879-88CT

Greenness map, AVHRR, August 11-20, 1990.

Advanced very high resolution radiometer

The advanced very high resolution radiometer (AVHRR) is one of several sensors aboard meteorological satellites operated by the National Oceanic and Atmospheric Administration. AVHRR data are collected in the visible, near-infrared, and thermal-infrared portions of the electromagnetic spectrum at a resolution of 1.1 kilometer (about 0.68 of a mile). Two satellites each make about 14 passes over the Earth in a 24-hour period, one in the morning and one in the afternoon. Thus, data are collected more frequently than Landsat data, but with much coarser resolution and for much larger areas.

The EROS Data Center has been receiving and processing 1-kilometer resolution data from the AVHRR system since 1987 and using them for a variety of land applications, such as drought monitoring, fire fuel assessment, and land surface characterization. The use of these data for management purposes complements the traditional use of 4- and 16-kilometer resolution AVHRR data for meteorological applications. Some AVHRR data are available on CD-ROM.

Comparison of Landsat sensors: Yellowstone National Park, Wyo., Landsat MSS, August 1972, and Landsat TM, August 1989. (Reduced to 68 percent)

SI1SSPA00820805

Los Angeles, Calif., SLAR mosaic compiled in April 1986 from radar strips flown in November 1985. (Reduced to 25 percent)

Side-looking airborne radar

Because SLAR systems provide their own energy to illuminate the ground, these images can be collected regardless of the weather or time of day, making such data valuable for mapping parts of the world that are perpetually cloud covered, such as the Amazon Basin. SLAR systems transmit microwave energy to the ground from aircraft. The signal strikes the ground and is reflected and scattered. The portion of the signal that returns to the sensor is recorded as digital values that can be represented on photographic film. The side-looking geometry of the system produces

shadows of varying lengths depending on the angle of illumination and the surface relief. Although these shadows enhance subtle terrain features, such as faults and folds, they also obscure land surface detail in the shadow area. SLAR images are useful to scientists studying geologic structures. SLAR images most often consist of image strips and 1:250,000-scale mosaics prepared from these strips. Some SLAR data are available on CD-ROM.

and May 1985. (Reduced to 43 percent)

E-1721-99CT

Display Images

The USGS has available aerial photographs and images suitable for framing that can be ordered without custom research. In this category are satellite images and aircraft photographs of selected States, cities, regions, and features within the United States; and of such natural phenomena as fires and volcanic eruptions. Some areas outside the United States are also covered. Some photographs taken on space missions by NASA astronauts are also available in this format.

Ordering Information

USGS aerial photographs covering the United States and worldwide satellite data from the early 1970's to the present can be ordered directly from the USGS. The USGS also has information about images available from other Government agencies and commercial sources. Indexes of aerial photographs and online information about satellite data are also available. For more information or to order any of the products in this booklet, call 1-800-USA-MAPS.

FOREWORD

The history of cartography comprises many technological breakthroughs that stand as milestones of our profession. The use of aerial imagery as a source for mapping represented a tremendous breakthrough for cartography. The use and introduction of airborne sensors for photogrammetric exploitation and feature identification continues to affect the production of geo-spatial information.

More recently, the introduction of Geographic Information Systems (GIS) has enabled cartographers to selectively portray various aspects of the earth and its surface by querying a data base populated with spatial and feature information. The fidelity of the resulting product is directly related to the quality of the information resident in the data base from which the query was drawn.

The Image Interpretation Course was produced under the auspices of the Integrated Training Working Group (ITWG) and approved by the Activation Control Team (ACT). The Photo Interpretation Training Working Group (PITWG) performed extensive research in the planning and development stages of the course. The PITWG was composed of representatives from Defense Mapping Agency-Aerospace Center, Hydrographic/Topographic Center, and Reston Center. The PITWG determined both course format and content.

The information contained in the Imagery Interpretation Course and the Student Handbooks will assist the trained image analyst in the accurate identification of physical and cultural features viewed on aerial imagery. The Imagery Interpretation Course Student Handbooks are part of a training course that was developed by the Defense Mapping Agency in recognition of the need to maintain a highly skilled and proficient cartographic work force.

The course developer staff at the Defense Mapping Agency includes:

George Szigeti, Cartographer. Mr. Szigeti produced Module 1, 2, and edited Module 3, 4, and 5. His expertise is based on a MS in Geological Engineering, 4 years experience as a topographic and terrain intelligence officer in the US Army Corps of Engineers, and at DMA on the AS-11 and FE systems for 11 years. His knowledge of physical and cultural geography and his knowledge of application software helped make the document a valued training resource.

Gregory J. Bushur, Cartographer. Mr. Bushur produced the majority of Module 2 and the Supplemental Handbook. His expertise is based on a B.S. in Geophysics, 3 years cryptographic and electronic engineering experience with the U.S. Marine Corps, 8 years engineering experience in private industry, and 6 years of experience on the Feature Extraction system. Without his knowledge of industrial processes, electronics, and surface transportation the cultural handbook would not have been possible.

II Photo Interpretation Principles

Stephen L. Wheat, Cartographer. Mr. Wheat produced the Airfield module. His expertise is based on a BS in Geography, 18 years experience as an Intelligence Officer, 2 years as an Imagery Intel. instructor for the USAF, and 12 years experience at DMA. His knowledge of airfields and experience as an Imagery Interpretation instructor has enabled him to produce the Airfield Module and assist in designing the overall structure of the course.

Chris Riopelle, Cartographer. Mr. Riopelle produced the Coastal Hydrography Module and the Climate Section of the Vegetation Module. His expertise is based on a BS in Meteorology and Earth Science, 2 years with the National Weather Service and 7 years experience at DMA. He has worked in Manual DTED compilation, Terrain Analysis, DE cartography and is now a DE Segment Production Engineer.

Debra L. Hinrichs, Cartographer. Ms. Hinrichs produced the Physiography and Inland Waterway Modules. Her expertise is based on a BS in Geology, and 8 years experience at DMA in Terrain Analysis and the Automatic Graphic Digitization System. Her contribution to the course made a significant difference.

Sandra Fleming, Computer Operator. Ms. Fleming assisted in the editing and formatting of the final documents. Her expertise is based on 15 years experience in DMA and she is nearing completion of undergraduate work in Geography. Her contributions helped make the document usable and understandable.

ACKNOWLEDGMENTS

The compilation and preparation of materials for the DMA Photo Interpretation Course involved much more than just the authoring of this student handbook. The other components of the photo interpretation library include the Photo Interpretation Illustrated Glossary, the teaching images, instructor image viewgraphs and templates, lesson plans and other instructional materials. The timely completion of this project would not have been possible without the assistance of our co-workers. We thank the following individuals for their assistance with the development of the Photo Interpretation Course:

A large number of images were required to cover the many cultural features discussed in Module 2. Mr. Paul Burrows used his experience as an image interpreter in the US Marine Corps and as an analyst on the FE and DE systems to locate and identify features on source imagery for inclusion in the teaching imagery set. He also assisted with the compilation of the instructor templates and maintenance of the feature/image database.

A substantial part of the image scanning for the teaching images and instructor viewgraphs was done via the Point Graphics Production System at St. Louis. Kerry Antoniewicz, Robyn Burris, Luther Claus, Laurence Englehard, David Nelson and Garth Sutton performed the scanning and formatting, volunteering to work second shift.

Technical expertise, proofreading and editorial support were provided by Sam Adamczyk, Cliff Hardin, Debbie Knox, Patti May, Tom Obelenus, Victoria Sanders, James Sarcinello, Todd Stovall, and Glen Tewkesbury. Brian Fleming and Tamara Warden assisted with text development and illustrations were prepared by Tobi Bordihn and Ellen Krafcsin. Terrance Moore played a significant part in the development of lesson plans.

Many more of our co-workers provided significant support to this effort, but it would be impractical to name them all. Nevertheless, their assistance is appreciated.

Finally, we wish to thank Steve Handwerk, Phyllis Farris, Rose Pangborn and Pat Hart for their roles in the administration of the project. They provided guidance and direction through the sometimes tumultuous history of this team.

CHAPTER 1 – INTRODUCTION

Photo interpretation, or more properly **image interpretation**, is something which we practice every day. We see images in books, newspapers and magazines, or on TV. Unconsciously, we interpret the information conveyed by these images in order to identify and gain information about the objects portrayed. The degree of success depends on a number of factors, including the type, scale and resolution of the image, and our familiarity with the subject.

As cartographers, we deal with that aspect of image interpretation known as **remote sensing**. Remote sensing is defined as the gathering of information about an object by means of a sensor at some distance from that object. For our purposes, this refers to an airborne or spaceborne sensor. This means that we are viewing objects from a vertical or a near-vertical perspective. Since we are used to looking at objects from a ground level, or horizontal, perspective, many familiar objects may become difficult to recognize.

The term **photo interpretation** has been handed down from the days when all remotely sensed imagery was in the form of black and white photographs. Since then, other types of sensors, both photographic and digital, have been developed to utilize the visible and invisible portions of the electromagnetic spectrum. The term **image interpretation** was adopted to cover all aspects of remote sensing. Since we will be dealing with black and white, panchromatic (representing only the visible part of the spectrum) imagery, we will label the process as photo interpretation, whether the source material is photographic or digital. We will reserve the term image interpretation for other sources, such as multi-spectral, infrared, and radar imagery.

Aerial Photo Examples

Aerial photo examples for many of these features are contained within the teaching imagery set. A data base (FileMaker Pro, for Macintosh) referencing the features to the imagery is included with the teaching materials.

Changes and Additions

The contents of this course are as complete and as current as the best sources available. Any corrections or information about new features, new configurations, or better image examples should be forwarded to:

Defense Mapping Agency
Process Improvement Office (ODGI)
Attn: Image Interpretation Training Team, Mail Stop L-54
3200 South Second Street
St. Louis MO 63118-3399
(314) 263-4547

CHAPTER 2 – PHOTO INTERPRETATION PROCESS

The type, quantity and quality of information that can be obtained by analyzing aerial photography is dependent on the background, knowledge, skill and interest of the photo interpreter. Those individuals with a broader range of experience find photo interpretation to be less difficult. The purpose of this course is to build on the individual cartographers' background by giving them instruction and practice in applying photo interpretation skills. As each individual becomes more skilled at photo interpretation, it is natural that their interest level will increase as their task becomes less frustrating.

There are several activities, or processes, that the photo interpreter performs during examination of the aerial photograph. These processes, in the order in which they are performed, are: detection, identification, and evaluation. In other words, photo interpretation is:

1. The art of knowing what you are looking for;
2. Identifying it when you find it; and
3. Knowing the significance of it in that location.

Measurement is also a part of the interpretation process, but is done at two different times and for different purposes; first, as an estimation of relative size to aid in identification, and second, as detailed measurements during the evaluation process.

Detection is the easiest part of photo-interpretation, in that it only requires the realization that there is something on the photo that is different from its surroundings. Local changes in the characteristics of the photo (tone, texture, pattern, etc.) distinguish objects from each other. The changes could be sharp and distinctive, allowing rapid visual discrimination. Other features are harder to detect because of their small size or because they are not distinct from their surroundings. In these cases, their presence must be inferred from more subtle visual clues, and a knowledge of what features should be found in a particular area. Other features may not be visible at all, but their presence is inferred through the identification of related features. The use of stereo models greatly enhances the photo interpreter's ability to detect features.

Identification of the feature is the next step in the interpretation process. Part of identification is a judgment of the feature's size, relative to the surrounding features. Knowing the relative size of an object determines what it may or may not be. Identification requires not only the use of clues provided by the imagery, but also a working knowledge of the types of features likely to be found in the area, and how they would look from the vertical perspective.

Some features are distinctive and readily identified. For other features, identification is an exercise in problem solving, using the different elements of photo

interpretation to identify features, or to identify object-complexes from their components. The problem solving process will be discussed in more detail in the section on Convergence of Evidence.

The evaluation process is the most difficult, and requires an in depth knowledge of both the features being considered, and the geographic area in which the features are located. For many DMA products, information on the size, construction, composition and function of a feature are required. Detailed measurements are easily made using modern stereoplotters. However, the rest of the information must often be inferred from scant visual clues, supplementary source materials and the background knowledge of the cartographer. Again, the analyst must resort to problem solving skills to provide the needed information. For cartographic purposes, detailed evaluations on the economic or political significance of most features is not needed. However, the military significance of features is a key consideration on some products.

This module will concentrate on using the clues provided by the imagery to locate, identify and evaluate features. Detailed information about the different classes of features depicted on cartographic products will be covered in the following modules.

CHAPTER 3 – ELEMENTS OF PHOTO INTERPRETATION

The visual clues provided by the aerial photograph can be grouped into eight categories: Size, Shape, Shadow, Tone, Texture, Pattern, Location and Associations. When we look at a photograph we use these elements in our interpretation. Some features can be quickly identified using only one of these elements; others require the use of several elements.

Size

One of the first judgments we make about an object we have located on a photograph is its size in relation to other nearby objects. Trees are larger than bushes, reservoirs are larger than swimming pools, and an apartment building is larger than a single family house. Most of the time there are readily recognizable objects on the photo for us to compare an unknown object to. In some cases, especially when dealing with aerial photos, we may need to make a judgment as to the scale of the image before we can identify anything. Whether we use a comparison, or a measurement, the relative size of an object is our first clue as to its identity.

Shape

The shape of an object is an important factor in its identification. The shape delimits the class of features to which the unknown object belongs. Sometimes the shape alone will conclusively identify the feature. The shape also yields information as to the structure, function and significance of the object being studied.

Regular shapes and patterns, straight edges, and square corners are almost always indicative of man-made (or man-modified) objects. The opposite normally indicate natural features. Many industries can be identified by the characteristic shapes of the buildings or equipment associated with that activity.

Although the shape of an object is an important clue to its identification, the shape when viewed from the vertical perspective (plan view) can be quite different than when viewed from the horizontal (profile or oblique views). The ability to visualize and identify objects in the plan view is an important skill for the cartographer to develop. Wherever possible in this course, plan view illustrations are provided to help familiarize the students with the shapes of objects from the vertical perspective.

Stereo viewing enhances our ability to recognize the features by revealing their three-dimensional shape. This is especially important when high sun angles minimize shadows.

Shadow

Shadows reveal information about the shape, size, and construction of features, and in some cases can yield an immediate identification.

The shape of some objects is difficult to determine, either because they are not distinct from their background, or because their size in plan view is very small (e.g., towers and pylons). In these cases, a good shadow will reveal the shape of the object, usually providing a silhouette similar to the familiar profile view. In some cases, the shadow is the best indicator of the feature's presence and identity.

Figure 1: Effect of slope and other factors on shadow length.

The shadow also provides an indication of the height of an object. This is especially important when viewing imagery monoscopically. Relative heights of objects can be quickly determined by comparing the length of their shadows. You must be careful when using shadows, however, as the slope of the ground and other factors, will affect the length of the shadow (Figure 1). The careful use of mensuration techniques will yield accurate values of height.

Shadows will also work against the analyst, hiding smaller features or the character of the ground's surface. Shadow areas should be studied carefully so that no significant feature is missed.

Tone

Tone is a measure of the amount of light reflected by an object. On a black and white image, this appears as shades of gray. The edges created by differences in tone allow us to distinguish between adjacent features, and define the shape and boundaries of these objects. The tone of an object is influenced by its composition, the angle at which the sun strikes the surface of the object, and the position of the sensor.

Smooth surfaces, such as water and glass, are excellent reflectors. They can be either light or dark in tone, depending whether they are reflecting the light toward or away from the sensor. Because stereo photographs are taken from different angles, such surfaces may appear very light on one image and almost black on the other.

On the other hand, rough surfaces reflect light in all directions, and will appear as intermediate gray tones, depending upon their composition. Those surfaces oriented toward the sun will appear lighter on both images, than surfaces oriented away from the sun.

Composition and color also affect the tone. Light colored materials, or objects painted in light colors, will have a lighter tone on the imagery than those with dark colors.

Tone is often used in analysis of vegetation. Coniferous trees are usually darker than deciduous trees. Differences in tone are used to distinguish between types of crops. Tone may also be an indication of soil types or soil moisture.

Areas of bare ground, or paved surfaces, will frequently show up as lighter than the surrounding ground surface. The smooth surfaces of pavements in particular will show up as light-toned areas. Fresh asphalt will appear darker in tone, but becomes lighter with age.

Areas of shallow water can often be detected by their lighter tones, particularly when the bottom material is a light colored sand or mud. When describing water bodies, they should be examined carefully for variations in tone.

Texture

Texture is the frequency of tonal changes across the image of a feature. Smooth texture is where the feature has a constant even tone. Fine texture represents rapid tone changes over short distances. Coarse textured features have a lesser frequency of tonal changes. Mottled texture refers to a blotchy appearance, with irregular blobs of different tones. Other terms used to describe texture include stippled, rippled and lumpy.

The texture of a given surface will vary with the scale and resolution of the imagery. As scale or resolution decrease, the apparent texture of a feature becomes finer. For example, large scale imagery of a forest has a mottled or coarse texture, with variations caused by individual leaves and branches. At a smaller scale, the forest would display a finer texture, where the variations are caused by the individual trees and their shadows. At a still smaller scale, where the resolution does not allow the distinguishing of individual trees, the forest may have a smooth texture.

Pattern

Pattern refers to the spatial arrangement of features in an area. Patterns may be regular, such as trees in orchards or urban street patterns, or irregular, such as the arrangement and alignment of streams. Patterns can be used to identify features (such as orchards) or to determine functions (military installations normally have a distinctive pattern in the arrangement of buildings). Drainage patterns often yield information about the nature of the underlying rocks and soil.

One of the advantages of aerial photography is that many patterns and associations not visible from the ground are readily visible in the plan view. The patterns are related to the function and/or origin of the feature. As with shape, regular, geometric patterns indicate the influence of man, while irregular patterns are frequently natural.

Associations

As mentioned before, vertical aerial photography reveals spatial relationships between objects in a manner that may not be obvious when viewed from the ground. This viewpoint also allows us to see a large area around the feature being examined, and use the information to help identify it.

Features, both natural and manmade, arrive on the earth's surface via an orderly set of processes. Their arrangement reflects the processes that placed them there, and, for manmade objects, often reflects their function as well. An appreciation of these orderly arrangements is developed through a thorough knowledge of the features in question.

When the identity of a feature is not obvious, we look at those features immediately surrounding the object we wish to identify. For instance, a large, single

story building's purpose may not be obvious when examined by itself. A large parking lot full of cars would indicate that it is a shopping center, while the presence of many trucks and a railroad siding could identify it as a warehouse, or the presence of raw materials would indicate a light fabrication facility. Aluminum processing requires large amounts of electric power, and a large transformer substation is always associated with these facilities. Military facilities and prisons will have security facilities such as fences, guard shacks and sometimes guard towers.

Location

Location is the regional aspect of associations. The appearance and occurrence of many features will vary in different parts of the world. Before starting their analysis, cartographers should be aware of the region they are working in, and how climate, availability of materials, local customs and economics affect the appearance of the features they are to identify. For example, schools in Asian countries look significantly different from schools in western countries. The type of vegetation you would expect to find depends upon what part of the world you are looking at.

In a local context, the area being studied can be broken down into subregions. The identity of features can then be judged on the basis of the subregion in which they occur. Cylindrical objects in an agricultural area are likely to be grain silos, but if they were located at a refinery or power plant they would probably be oil or gas tanks. A large building in a military base could be an administration building, but if it were in a residential area it could be a school.

Factors such as topography, soils and geology, vegetation, and cultural effects must be considered. Radar sites are normally located on high ground to minimize terrain interference, thermal power plants must be located near supplies of water for cooling, and vegetation types may vary depending on the direction the slope is facing.

Seasonal Effects

When performing photo interpretation, it is also important to consider the time of year the imagery was recorded. The date of the imagery should be determined before any interpretation is started. Seasonal changes can have a substantial effect on the appearance of objects, particularly natural features. Information about the climate and seasonal changes in the area being studied is needed.

In areas of deciduous vegetation, the loss of leaves from the trees in the winter (or dry season) can lead to erroneous estimations of tree height or canopy closure, but estimates of tree spacing and trunk diameter are easier to obtain. In addition, features normally concealed by the canopy are readily visible. Contours or ground elevation data can be collected more accurately when the canopy does not hide the ground.

Elements of Photo Interpretation

Photo Interpretation Principles 9

Characteristics of drainage features will vary with the seasons. Intermittent streams and ponds may be filled with water during the wet seasons, leading to their erroneous classification as perennial. Water levels in lakes, ponds and rivers may vary considerably during the year. Ancillary sources must be consulted to insure that the predominant conditions are portrayed properly.

Snow cover can conceal many important features. Small streams may be frozen and covered in snow. Roads may be plowed, but accurate road widths, and often road surface type, cannot be determined. Snow remains longer on shaded slopes, and thus may decrease the contrast. A reversed effect can result, with the shadow side of hills and ridges appearing lighter than the sunlit sides.

CHAPTER 4 – PROBLEM SOLVING

Responsibilities of the Photo Interpreter

No one is an expert in all the fields of knowledge that a modern cartographer has to deal with, but that should not lead to complacency. The best photo interpreters are those that continually educate themselves, seeking to improve their ability to perform their job. There are certain key traits and skills that a photo interpreter should strive to develop:

1. An awareness of the characteristics and limitations of the source imagery.
2. A thorough knowledge of the characteristics of agriculture, industry, transportation, living customs, civic planning, military organizations and equipment, hydrography, vegetation and natural terrain features.
3. A positive attitude. Photo interpretation requires a scientific approach. Common sense, disciplined study, research and experience are prerequisites for proficiency. Solutions to all questions are not easily obtained; but with a positive attitude and knowledge of the subject material, the qualified photo interpreter can produce a detailed and accurate analysis.
4. Communication with fellow cartographers. The individual analyst must keep in contact with others working in the same area to insure consistency in their interpretation and representation of features. One individual may have access to a particular source of information, or may have experience in a particular field or geographic area, or may have a particularly good example of a feature on his imagery, which would give other analysts the insight they need to identify problematical features.

The quality of the product generated by the cartographer is dependent on four factors: the quality and resolution of the imagery; the facilities and equipment available to the analyst; the amount of time available; and, most important of all, the ability of the interpreter. The first three factors are generally out of our control, but the fourth is entirely within our influence.

Ancillary Materials

Maps are graphic representations of the aerial view of the earth's surface. They provide a guide to what features are present, and their spatial relationship to each other. Studying maps will give you experience in the visualization of features from the vertical perspective. During photo analysis, a map, even one which is out-dated, is an excellent guide to the area being studied. It may help you identify features unfamiliar features, and helps you to remain properly oriented within your area.

As mentioned above, texts and other sources that document the local climate and seasonal changes should be consulted whenever working in a new area. Local cultural factors also must be considered. The skilled analyst knows when to seek additional information from ancillary sources. Magazine articles and travel brochures can be as helpful as texts and intelligence documents.

No single cartographer can hope to know everything about all the different types of features he may encounter. This emphasizes the need for an adequate library of reference materials to which the cartographer can turn. Each individual can contribute by collecting items that they find helpful. The pooled resources and experience of a team of analysts will usually be enough to solve even the most difficult interpretation problems.

Convergence of Evidence

Although many features can be readily identified using one or two of the previously mentioned factors, some features require the use of several lines of evidence to make an identification. Further analysis of features, to include determination of composition, structure and function, also usually require reference to different sources of information. The analyst uses these different sources and lines of reasoning to converge at the correct answer.

A methodical approach is required to most efficiently analyze an area. The cartographer should start with generalities and go on to details. Always evaluate the known features before attempting to identify the unknown.

The first step in the analysis of an aerial photograph is to orient the photo to the best available map source. Once the analyst has determined what area on the map is covered by the particular image, he has established a framework of features upon which to build his interpretation. A quick check is made at this point to insure that all prominent features are in their correct locations.

The area being studied is then scanned and the general character of the area is noted. The area is divided into subregions if appropriate (e.g., mountains vs. plains, forests vs. prairies, urban areas vs. agricultural areas, etc.). The classification of the subregions helps to determine the kind of features liable to occur in those areas.

Large area features and major lines of communication are defined to help orient the analyst, and to form a framework for the detailed evaluation. The analyst works across the image evaluating known features. Then unknown features are identified through their associations with those previously identified. The elements of photo interpretation described earlier are used to generate probable answers to questions, and a critical evaluation of the evidence indicates the choice with the highest probability of being correct.

Estimations of Density and Composition

Many cartographic applications require an estimation of feature density or percent composition. Some common problems are: canopy closure in forested areas; determining percentages to discern between deciduous, coniferous or mixed tree areas; percentage roof cover in built-up areas; and density of scrub or brush. There are several techniques for deriving this information, ranging from quick, visual approximations to more time consuming sampling techniques. Several of these methods are described here. The analyst can choose the best method for the product being compiled.

Visual estimation is the quickest method for determining densities and composition. However, it is also the most difficult for the inexperienced analyst. The best way to perform a visual estimation is with a comparison chart. Comparison charts can be constructed illustrating the critical percentage breakouts for the particular application.

Figure 2 shows breakouts at 10%, 25%, 50% and 75%, values used for defining canopy closure in tree areas. Different products may use different values, and another chart may be needed.

Sampling techniques involve measuring small portions of an area and extrapolating the results to the entire area. Sampling methods assume an approximately uniform distribution of the item in question, so that the area being measured is representative of the entire area. If the density changes across an area, it should either be separated into two areas, or the density estimates for the parts should be averaged together. The product specifications would decide which method to use.

The most common method used for determining percentages is the point count method. To determine the percentage by the point count method, an evenly spaced grid is placed over the area to be sampled. The grid intersections are used as sampling points. For simplicity in calculation, a 10 by 10 grid is used, yielding 100 sampling points (see Figure 3). To determine a percentage, just count the number of points that fall on the item being measured (tree canopy in Figure 3), and this number equals the percentage of that item in the given

Figure 2: Density Comparison Chart
(Percentage represents black area).

Figure 3: Density by Point Count

Figure 4: Composition by Point Count

area, in this case, 35% tree canopy cover. As demonstrated in Figure 3, using half of the grid (50 points) and multiplying by 2, or one fourth of the grid (25 points) and multiplying by 4 will also give an acceptable approximation of percentages.

Figure 4 illustrates how the point count method can be used to determine percentage composition. In this area there are two types of trees. Thirty two percent

of the area is coniferous, and sixteen percent is deciduous for a total canopy closure of forty eight percent. Fifty two percent is open ground. Two thirds (67%) of the trees are coniferous and one third (33%) are deciduous.

Figure 5: Sample Area Density Calculation

When the items being measured are more or less uniform in size (e.g., tanks, houses, orchard trees, etc.), measuring a small area and counting the number of items in that area can quickly yield a percentage. Just multiply the area of one item by the number of items in the sample area, and divide the product by the area of the sample (see Figure 5). For quicker computation, an accurate approximation of the area of a circle is given by the formula:

$$\text{Area} = 0.8 \times \text{Diameter}^2$$

CHAPTER 5 – LIMITATIONS OF PANCHROMATIC IMAGERY

The resolution of the imagery affects the ability of the analyst to identify and analyze features. The resolving power of an imaging system depends on two factors, the minimum size of an object that can be detected, and the ability of the system to detect tonal differences. There are many variables that affect the resolution of imagery, depending on the type of sensor (digital versus photographic), optical configuration, film or sensor sensitivity, the wavelength of radiation used, etc.

The minimum size of objects detected is described by the Ground Resolved Distance (GRD) for photographic systems, and Ground Sample Distance (GSD) for digital sensors. Both are an indication of the smallest object that can be separated from a neighboring object. When comparing photographic to digital sources, the values for GRD and GSD are interchangeable.

Another method for describing the spatial resolution of imagery is the National Imagery Interpretability Rating Scale (NIIRS), developed by the CIA's National Photographic Interpretation Center (NPIC). This method rates imagery on a scale of 1 to 9, with larger numbers signifying a greater resolution.

Although an object may be smaller than the resolution of the imagery, its presence can sometimes be inferred. The power transmission lines or telephone lines stretched between pylons may not be visible, but their presence can be inferred because of the presence of the pylons. At a smaller scale, the pylons themselves may not be visible, but a cleared way through a forest with no associated road or railroad would imply the presence of the power line and pylons.

The ability to detect tonal differences varies with the sensitivity of the sensor, and the wavelengths of radiation being used. Near infrared wavelengths, for instance, are much better for discerning between different types of vegetation. Wavelengths near the blue end of the spectrum are better for detecting areas of shallow water and underwater hazards.

CHAPTER 1 – INTRODUCTION

Contents

This module deals specifically with man-made features. Features including and relating to buildings and built-up areas, transportation facilities, industries, communications, etc. are included. A few man-made or man-modified features, such as orchards and reservoirs, have been left to other modules where the logical relationship is more appropriate.

An in depth explanation of airfields, facilities and navigational aids is given in Module 6, Aeronautical Data Maintenance.

The explanations of many features go beyond that which is photo-identifiable. This information is included to give the student a better understanding of the subject so that these features can be more readily identified when found in non-standard configurations or unusual locations.

Organization

This module has been organized so that it follows a logical progression. Information on basic features, such as buildings and transportation is presented first, followed by industries, communication, and cultural areas. The sequence within each section proceeds from general to specific information.

Features have been presented, as far as possible, in functional groupings. This results in some repetition between sections, but the relationships within these groups are important clues to the identification of many features.

A list of terms and their definitions is included after some sections. In addition to words used within the handbook, terms which the analyst may encounter in source references are included.

Sometimes, DMA specifications define a term differently than the general usage, or different definitions are used for different products. Notes to this effect are presented in *italics*.

This student handbook is unclassified. A classified supplement to the handbook is available. The supplement contains additional information derived from classified sources. Reference is made to the supplement in those sections of the handbook where additional, classified material is available.

CHAPTER 2 – BUILDINGS

General

Buildings, no matter what their function, have certain characteristics. These characteristics affect the appearance of the building, and often give clues as to its function. In this section, we will examine building structure types, roof types and construction materials. Identification of building functions will be covered in subsequent sections.

Physical considerations dictate the limitations on building construction and structural characteristics. The type of construction used is dependent on the size and purpose of the building, the cost and availability of construction materials, and the cost and availability of labor and technology. Buildings with the same function will usually be of similar appearance, as the function will dictate certain characteristics. However, geographic differences occur due to the availability of, or lack of construction materials, labor and technology. Building ornamentation also varies due to cultural differences, causing superficial differences in appearance. The successful analyst takes all of these factors into consideration when studying a built up area.

Building Structures

Building structures are classified by the way in which the weight of the building is supported. The most common structural types are framed construction, load bearing wall construction and composite construction. Stressed skin construction is used mostly for light framed structures such as storage buildings. Pneumatic buildings are inflatable structures, normally used as temporary or portable facilities.

Structural Supports

Column and Lintel

In column (or post) and lintel construction, support for the structure is provided by columns or load bearing walls. Various types of structures transmit the weight of the roof or upper floors to the supports. The simplest, and most common method is the column and beam structure. A series of horizontal beams, composed of steel, reinforced concrete or wood support the weight of the roof, and in turn are supported by columns. The columns may be composed of steel, masonry, reinforced concrete or wood.

A truss is used where a simple beam is not strong enough to bear the necessary load, especially where increased floor space between columns is needed. Trusses are normally steel, but may be wood (especially in smaller buildings, e.g. the rafters in single family houses) or reinforced concrete. Truss structures also allow
